Saw Dust Ash as Partial Replacement for Cement in Concrete

INTRODUCTION
There is need for affordable building materials in providing adequate housing for the teeming populace of the world. The cost of conventional building materials continue to increase as the majority of the population continues to fall below the poverty line. Thus, there is the need to search for local materials as alternatives for the construction of functional but low-cost buildings in both the rural and urban areas. Some of the local materials that have been used are earthen plaster (Svoboda and Prochazka, 2012), lateritic interlocking blocks (Raheem et al., 2012) and Palm kernel shell (Raheem et al., 2008).

Continuous generation of wastes arising from industrial by-products and agricultural residue, create acute environmental problems both in terms of their treatment and disposal. The con-

THIS RESEARCH CONSIDERED THE USE OF SAW DUST ASH AS A POZZOLAN IN THE PRODUCTION OF CONCRETE.

the study investigated the physical properties and chemical composition of saw dust ash (SDA) as well as the workability, and compressive strength properties of the concrete produced by replacing 5%, 10%, 15%, 20% and 25% by weight of ordinary Portland cement with SDA. Slump and compacting factor tests were carried out on the fresh concrete and compressive strength test on hardened concrete. The concrete cubes were tested at the ages of 3, 7, 28, 56 and 90 days. The results showed that SDA is a good pozzolan with combined SiO₂, Al₂O₃ and Fe₂O₃ of 73.07%. The slump and compacting factor decreased as the SDA content increased indicating that concrete becomes less workable as the SDA content increased. The compressive strength decreased with increasing SDA replacement. The compressive strength of concrete with SDA was lower at early stages but improves significantly up to 90 days. An optimum value of 23.26N/mm² at 90 days was obtained for concrete with 5% SDA replacement. It was concluded that 5% SDA substitution is adequate to enjoy maximum benefit of strength gain.

struction industry has been identified as the one that absorbs the majority of such materials as filler in concrete (Antiohos et al., 2005). If these fillers have pozzolanic properties, they impart technical advantages to the resulting concrete and also enable larger quantities of cement replacement to be achieved (Hossain, 2003). Appropriate utilization of these materials brings ecological and economical benefits.

Saw dust is a waste material from the timber industry. It is produced as timber is sawn into planks at saw mills located in virtually all major towns in the country. This process is a daily activity causing heaps of saw dust to be generated after each day. The need to convert this waste product into a useful by-product is the focus of the study. Some industrial wastes have been studied for use as supplementary cementing materials such as Fly ash (Sid-dique, 2004; Wang and Baxter, 2007; Wang et al., 2008), Silica fume (Lee et al., 2005; Turker et al., 1997), Pulverized fuel ash (Balandren and Martin-Buades, 2000), Volcanic ash (Hossain, 2005), Rice husk ash (Waswa-Sabuni et al. 2002) and Corn cob ash (CCA) (Adesanya and Raheem, 2009a; 2009b; 2010; Raheem and Adesanya, 2011; Raheem et al. 2010). Literature is however scarce on the use of saw dust ash.

Elinwa and Ejeh (2004) considered the effect of the incorporation of waste incineration fly ash (SWIFA) in cement pastes and mortar. Cheah and Ramli (2011) investigated the implementation of wood waste ash as a partial cement replacement material in the production of structural grade concrete and mortar. Elinwa et al. (2008) assessed the fresh concrete properties of self-compacting concrete containing sawdust ash. Elinwa and Mahmood (2002) considered ash from timber waste as cement replacement material. The present study considered both fresh and hardened properties of normal concrete in which saw dust ash is incorporated at the point of mix.

The study was performed in Nigeria which is in South-East Europe. The country has thick forests with abundant trees from which saw dust is obtained during processing. Thus, there is an abundant raw material for the research.

The current practice with saw dust is as fuel for domestic cooking and for sand filling ditches in which case it constitutes environmental nuisance. Converting the waste product - saw dust, into a useful by product – saw dust ash (SDA), has dual benefits. Environmental pollution is controlled and job is created for our teaming unemployed youths who could become agents for supplying the SDA to concrete industries that needed it. In the long run, the use of SDA as partial replacement for cement is expected to bring about reduction in the cost of concrete production since cement is the most expensive constituent of concrete. This study examined the use of saw dust ash as partial replacement for ordinary Portland cement in concrete. It involves the determination of the chemical composition of the ash and evaluation of the workability, and compressive strength of the concrete.

Materials and Method

Materials

The saw dust used for this study was collected from saw mill points at Apake in Ogbomoso, Oyo State, Nigeria. The Sample was carefully collected to avoid mixing the saw dust with sand. The collected sample was burnt into ashes by open burning in a metal container. The saw dust ash (SDA) was ground after cooling using mortar and pestle. The yield calculation was done and tests were carried out to determine the physical and chemical properties of the SDA. The SDA was taken to Lafarge Cement, West Africa Portland Cement Company (WAPCO) Sagamu, Ogun State, Nigeria, for chemical analysis using X-ray fluorescent analyser (Model QX 1279). The SDA particles passing through sieve of aperture 425µm was used for this study.

The Ordinary Portland cement (Dangote, Brand) used was obtained around under G area in Ogbomoso. Sharp sand was used as fine aggregates and granite with maximum size of 20mm as coarse aggregates. The fine and coarse aggregates used were obtained from a local supplier in Ogbomoso, Nigeria.

Specimen Preparation

SDA was used to replace ordinary Portland cement at 5%, 10%, 15%, 20% and 25% by weight of cement. Concrete with no SDA present serves as the control experiment. The mix ratio used was 1:2:4 (binder, sand and granite) with water to binder ratio of 0.5 which was later increased to 0.6. Table 1 showed the mix proportion for each category of SDA concrete.

Table 1 Mix proportions for SDA concrete

Sample was carefully collected to avoid activity causing heaps of saw dust to be generated after each day. The need to convert this waste product into a useful by-product is the focus of the study.
Slump and compacting factor tests were carried out to check the effect of SDA on the workability of fresh concrete. The tests were carried out in accordance with the requirements of BS 1881: Part 102 (1983) for slump test and BS 1881: Part 103 (1983) for compacting factor test.

Specimen preparation for compressive strength test was performed using 150mm cube steel moulds. The specimens were cast in three layers, each layer being tamped with 35 strokes of the tamping rod spread uniformly over the cross section of the mould. The top of each mould was smoothened and levelled and the outside surfaces cleaned. The moulds and their contents were kept in the curing room at temperature of 27 + 5°C and relative humidity not less than 90% for 24 hours.

De-moulding of the cubes took place after 24 hours and the specimens were transferred into water bath maintained at 27 + 5°C in the curing room. Compressive strength was determined at curing age 3, 7, 28, 56, and 90 days. The compressive strength was determined using compression machine with maximum capacity of 1500kN (Model 50- C34AC and Serial no 02094910). The strength value was the average of three specimens.

Results and Discussion

Chemical Composition
Table 2 shows the elemental oxides present in the SDA sample. The result showed that SDA has combined percentages of (SiO$_2$ + Al$_2$O$_3$ + Fe$_2$O$_3$) of 73.07% which is more than 70%, indicating that it is a good pozzolanic material in accordance with the requirements in ASTM C 618 (1991). The SDA has slightly lower silica content with a SiO$_2$ of 65.75% as against that of SWIFA which is 67.20% (Elinwa and Ejeh, 2004) and CCA with a value of 66.38% (Adesanya and Raheem, 2009a).

Physical Properties of SDA
Figure 1 shows the grading curve of the SDA. The curve falls within the sand zone of the particle size distribution curve stretching from the fine division to the coarse division. The result showed that SDA contains 55% of particles in the fine sand division. The material falls within zone 2 of the grading curve according to Elinwa and Ejeh [2004]. The specific gravity, yield and other physical properties of SDA are presented in Table 3. The result shows a specific gravity of 2.19 which is lesser than that of cement which has a specific gravity of 3.01.

Sieve Analysis of Aggregates
The results of the sieve analysis for fine and coarse aggregates are presented in Figures 2 and 3 respectively. It could be observed from Figure 2 that the coefficient of uniformity (C$_u$) and coefficient of curvature (C$_c$) for fine aggregates are 4.95 and 1.24 respectively. Thus, the sand can be said to be well graded (Smith and Smith, 1998). Similarly, the C$_u$ and C$_c$ for coarse aggregates are 0.89 and 1.75 respectively as obtained from Figure 3. This shows that the granite is uniformly graded (Smith and Smith, 1998). It can be concluded that the fine and coarse aggregates are suitable for making good concrete.

Workability
The results of the slump and compacting factor, indicating the workability of the SDA concrete are shown in Table 4. The table indicates that the slump value decreases as the SDA content increases. The compacting factor also decreases as the SDA content increases.
Figure 1: Particle Size Distribution Curve for SDA

Figure 2: Particle Size Distribution Curve for Fine Aggregates

Figure 3: Particle Size Distribution Curve for Coarse Aggregates
From these results, it was noticed that concrete became less workable as the SDA percentage increases meaning that more water is required to make the mixes more workable. This was what led to increasing the water binder ratio from 0.5 to 0.6 for the 20% and 25% substitution since the mix was becoming stiff.

The high demand for water as SDA increases is due to increased amount of silica in the mixture. This is typical of pozzolan cement concrete as the silica-lime reaction requires more water in addition to the water needed during hydration of cement (Hague and Kayali, 1998; Waswa-Sabuni et al. 2002; Adesanya and Raheem, 2009a).

**Compressive Strength**

The effect of curing ages on the compressive strength of SDA concrete is presented in Figure 4. The figure indicates that compressive strength generally increases with curing period and decreases with increased amount of SDA.

The result at 3 days showed a decrease in strength from 14.22 N/mm² for control to 5.41 N/mm² for 25% SDA replacement. Similar trend was observed at 7 days as shown in Figure 4. These results indicate that concrete containing SDA gain strength slowly at early curing age. This is in line with previous findings that concrete containing pozzolanic materials gained strength slowly at early curing ages (Hossain, 2005; Adesanya and Raheem, 2009a).

At 28 days, there was continuous increase in compressive strength for all the classes of concrete with values ranging from 20.52 N/mm² for the control, to 7.48 N/mm² for 25% SDA replacement. The control still has the highest compressive strength at this age.

The result at 56 days indicated that pozzolanic action had commenced as evident from the higher percentage increase in compressive strength by SDA concrete over that of the control. The percentage increase with respect to the 28 day strength for control was 3.61%, while it was 21.87%, 5.99%, 7.94%, 0.80% and 9.89% for 5%, 10%, 15%, 20% and 25% SDA replacements. This increase in compressive strength can be attributed to the reaction of SDA with calcium hydroxide liberated during the hydration of cement.

At 90 days, there was significant improvement in strength development beyond 56 days as shown in Figure 4. The percentage increase in strength from 28 to 90 days was between 18.82% and 63.57%. Higher percentage increases in strength than at 56 days were observed confirming the cement that continues to hydrate. However, the significant increase in strength of SDA concrete is due to the pozzolanic reaction of SDA.

Table 4: Slump and compacting factor values of SDA Concrete
The strength gain can be attributed to the cementitious products formed as a result of hydration of cement and those formed when lime reacts with the pozzolan incorporated (Balendran and Martin-Buades, 2000; Adesanya and Raheem, 2009a). An optimum value of 23.26 N/mm² at 90 days was obtained for concrete with 5% SDA replacement. It was concluded that 5% SDA substitution is adequate to enjoy maximum benefit of strength gain.

Figure 5 showed the effect of SDA percentage replacement on the compressive strength of concrete. As could be observed from the figure, there is a general decrease in compressive strength as the SDA content increases. Since all the specimens meet the minimum strength of 6 N/mm² after 28 days of curing recommended by BS 5224 (1976) for masonry cement, SDA concrete could be used for general concrete works where strength is of less importance such as in mass concrete, floor screed and mortar.

Conclusion

From the results of the various tests performed, the following conclusions can be drawn:

SDA is a suitable material for use as a pozzolan, since it satisfied the requirement for such a material by having a combined (SiO₂ + Al₂O₃ + Fe₂O₃) of more than 70%.

Concrete becomes less workable as the SDA percentage increases meaning that more water is required to make the mixes more workable. This means that SDA concrete has higher water demand.

The compressive strength generally increases with curing period and decreases with increased amount of SDA. Only 5% SDA substitution is adequate to enjoy maximum benefit of strength gain.
