Patch loading - analytical approach to critical load determination

The problem of plate stability under patch-loading can be analyzed using a variety of mathematical models by which the problem can be more or less realistically described. Models adopted in this paper serve as the basis for checking applicability of the analytical solution when subjected to complex load conditions. The accuracy of the procedure, proven by comparison with the data obtained through numerical models, and achieved by introduction of the exact stress function and use of appropriate deflection functions, confirms correctness of the solution presented in the paper.

Key words:
elastic stability of plates, exact stress function, mixed boundary conditions, patch loading

1. Introduction

In steel structures, buckling problem of the high steel girders under variable external loads is still very interesting topic. Presently available literature abounds with data regarding this problem, but mostly obtained by numerical or experimental methods. Analytical approach has been avoided mostly because of unknown stress distribution.

Analytical approach to critical load determination based on exact stress functions implementation, is verified for relatively simple case of plate under (DEA) compression [3-5]. In this paper the next step is introduced through a significantly complicated problem of the plate under locally distributed stress (patch loading) applied on the upper flange of the steel girder. That way, the applicability and accuracy of introduced analytical approach can be proven on a more demanding and near to real life engineering problems.

Comparative analysis of the four models defining stability problem of rectangular plates with different boundary conditions under patch loading, can point to interesting conclusions about the relevance of various parameters and their influence on the value of the critical load.
2. Basic outline

Analytical approach to stability problems of the plates due to the patch-loading begins with determination of exact stress functions for selected models. In the previous paper [5] it has been already explained that any arbitrary load (normal and/or shear) which acts along the edges of the plate, can be described by the chosen functions (even and/or odd in relation to the coordinate axes), so the total solution is obtained by the adequate combination of eight basic cases (Figure 3).

For the presented initial models, external load is obtained by combining symmetrical (DEA) and anti-symmetrical (DEB) basic types (Figure 3). Since the results for stress functions for the DEA case can be found in literature [3-5], only DEB case is presented in this paper.

In the Figure 4, the procedure for obtaining the exact stress distribution for the model 2 is explained by superposition of the adequate DEA and DEB solutions. The possibility to achieve exact stress functions for complex cases of plates under patch loading guarantees accurate analytical approach to critical load determination. So far, in the literature, only in the researches of Pavlovic and Liu [3, 6, 7] it is possible to find analytical results for buckling loads, but exclusively for simply supported plates. Up to now, for this load case and the plates with different boundary conditions, there are no precise analytical solutions.

In this paper, two mathematical models are used to prove accuracy of presented analytical approach. All the results in this paper are reaffirmed by numerical finite-element (ANSYS) runs.

2.1. Mathieu’s solution

Although basic equations can be found in literature [1-5], before proceeding with solution it is necessary to summarize the main governing expressions of two-dimensional elasticity, since Mathieu’s notation and approach (XIX century work) depart from current conventions. In his paper [1], Mathieu expressed the known equilibrium equations, without the presence of body forces, in terms of displacements:

\[
\Delta u = \frac{1}{\varepsilon} \frac{d v}{d y} \quad (1a)
\]

\[
\Delta v = \frac{1}{\varepsilon} \frac{d u}{d x} \quad (1b)
\]

where:

- Laplas operator
- \( u, v \) - shifts in \( x \) and \( y \) direction respectively
- \( \nu = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \) - volume dilatation
- \( \varepsilon = \frac{\mu}{\lambda + \mu} \) - constant defined using familiar Laméovih parameters

Mathieu's notation and approach depart from current conventions. With the quite simple mathematical operations system (1) can be transformed into the following form:

\[
\Delta v = 0 \quad (4)
\]
Mathieu’s approach to the 2D elasticity problem starts with the careful selection of two ordinary Fourier series for \( v \) (4) with infinite unknown coefficients, taking into account the symmetry or anti-symmetry of the stresses with respect to the \( x \) and \( y \) directions.

\[
v = v_1 + v_2 \tag{5}\]

The following step presents the introduction of the function \( F (F_1 + F_2) \) from the conditions that the equation is fulfilled:

\[
\Delta F = \frac{1}{\varepsilon} v \quad \Rightarrow \quad \Delta F_1 = \frac{1}{\varepsilon} v_1 \\
\Delta F_2 = \frac{1}{\varepsilon} v_2 \tag{6a} \tag{6b}
\]

Finally, when displacements \( u \) and \( v \) are determined

\[
u = \frac{\partial f}{\partial y} \quad \Rightarrow \quad \frac{\partial f}{\partial y} = \frac{v}{\varepsilon} \tag{7a} \tag{7b}
\]

where:

\[
\alpha = (\lambda + 2\mu) / \mu \quad \text{constant expressed with Lamé parameters}
\]

normal stresses \( N_i \) and \( N_j \) are defined along the axes \( x \) and \( y \), as well as the in-plane shear stress \( T_{ij} \).

\[
N_i = \lambda v + 2\mu av_i + 2\mu \frac{\partial^2 F}{\partial x^2} \tag{8a} \tag{8b}
T_{ij} = \mu \left[ 2 \frac{\partial^2 F}{\partial x \partial y} + \alpha \left( \frac{\partial v}{\partial y} \right) + a \left( \frac{\partial^2 v}{\partial x \partial y} \right) \right] \tag{8c}
\]

As it is pointed above, Mathieu’s solution for the basic case DEB has already been presented [3, 4, 5]. In this paper, special attention is paid to the second load case (DEB), with all necessary explanations and comments.

2.2. Exact stress function for the fundamental load case (DEB)

Obviously, DEB case is not in self-equilibrium and involves rigid-body translation.

**DEB - boundary conditions:**

\[
N_x = f(y), \quad x = \pm b/2 \tag{9a} \tag{9b} \tag{9c}
N_y = 0, \quad y = \pm b/2
T_{xy} = 0, \quad x = \pm b/2, \quad y = \pm b/2
\]

**external load:**

\[
f(y) = A_0 + \sum A_i \cos ny \tag{10}
\]

**Introduction of the series**

In this case, series odd in \( x \) but even in \( y \) must be chosen for the dilatation functions.

\[
v_1 = Ox + \sum B_i \, e(ny) \cos ny, \quad n = \frac{2q\pi}{b} \tag{11a} \quad q = 1, 2, 3, \ldots
v_2 = \sum \beta_n \, E(mx) \sin mx, \quad m = \frac{p\pi}{a} \tag{11b} \quad p = 1, 3, 5, \ldots
\]

Therefore, the expressions for \( F_1 \) and \( F_2 \) are:

\[
F_1 = -\frac{D}{6b} x^2 - \frac{1}{2\varepsilon} \sum B_i \, e(nx) \cos ny \quad + \sum H_i \, e(nx) \cos ny \tag{12a}
F_2 = \frac{1}{2\pi} \sum \beta_n \, ye(my) \sin mx \quad + \sum G_n \, E(my) \sin mx \tag{12b}
\]

In the aim of more efficient writing of very long expressions, certain abbreviations are introduced (\( E(\ ) = \cosh(\ ) \) and \( e(\ ) = \sinh(\ ) \)).

**Boundary conditions**

From the boundary condition of \( T_{ij} = 0 \) on \( x = a/2 \), the following expression for \( H_i \) is obtained:

\[
H_i = B_i \left[ -\frac{1}{2m^2} + \frac{a}{4m^2} E(\pm mb) \right] \tag{13a}
\]

Components containing \( \cos \frac{1}{2} ma \) can be eliminated with the proper selection of the parameter \( m = p\pi/a, \quad p = 1, 3, 5, \ldots \). Similarly, from the boundary condition of \( T_{ij} = 0 \) on \( y = b/2 \), and noticing that \( \sin \frac{1}{2} nb = 0 \) for the values \( n = 2q\pi/b, \quad q = 1, 2, 3, \ldots \), the expression for \( G_n \) follows:

\[
G_n = \beta_n \left[ -\frac{1}{2m^2} + \frac{b}{4mc^2} E(\pm mb) \right] \tag{13b}
\]

The second group of the boundary conditions is used to produce infinite system for constants \( B_i \) and \( \beta_n \). Therefore, considering equations (13), the boundary condition of \( N_x = f(y) \) on \( x = a/2 \) yields:

\[
\frac{(\lambda + 2\mu) Da}{2(\lambda + \mu)} + \sum B_i \left[ \frac{e(\pm na)}{2 E(\pm na)} \right] \cos ny + \sum \beta_n \left[ \frac{1 - \frac{mb}{E(\pm mb)}}{2} \right] E(my) = \sinh(\ ) \tag{14a}
\]

Similarly, the fourth condition of \( N_x = 0 \) on \( y = b/2 \) results in:

\[
\frac{1}{(\lambda + \mu)} \sum \beta_n \left[ \frac{1 - \frac{mb}{E(\pm mb)}}{2 E(\pm mb)} \right] e(nx) = \cos nb \tag{14b}
\]

**Coefficients** \( B_{mn} \) and \( B_{nb} \) Multiplying by \( dy \) and integrating between \( \pm b/2 \), equation (14a) reduces to its first term:

\[
D = \frac{2A_i}{(\lambda + 2\mu)a} \tag{15}
\]
At the end, final expression for coefficients are introduced:

\[ B_i = \frac{A_i}{(\lambda + \mu)(\lambda + 2\mu)} \sum \frac{1}{\pi} \lambda_i \psi \left(\frac{p}{2\pi}\right) \times \] (17a)

\[ \times \lambda_i(p,q) + (16\psi_0 / \psi^2) \Lambda_1(p,q) + (16\psi_0 / \psi^2) \Lambda_1(p,q) + \ldots \]

At one another to solve "exactly" infinite system of equations.

\[ B_i = \frac{A_i}{(\lambda + \mu)} \sum \frac{1}{\pi} \lambda_i \psi \left(\frac{p}{2\pi}\right) \times \] (17b)

\[ \times \lambda_i(p,q) + (16\psi_0 / \psi^2) \Lambda_1(p,q) + (16\psi_0 / \psi^2) \Lambda_1(p,q) + \ldots \]

Finally, expressions for the exact stress functions for the plate under load case (DEB) are:

\[ N_1 = \frac{2A}{a} x + (\lambda + \mu) \sum B_i \Bigg[ 1 - \frac{1}{2} E \psi \left(\frac{p}{2\pi}\right) \psi \left(\frac{q}{2\pi}\right) \times \] (20a)

\[ \times \lambda_i(p,q) + (16\psi_0 / \psi^2) \Lambda_1(p,q) + (16\psi_0 / \psi^2) \Lambda_1(p,q) + \ldots \]

\[ N_2 = \frac{2A}{a} x + (\lambda + \mu) \sum B_i \Bigg[ 1 - \frac{1}{2} E \psi \left(\frac{p}{2\pi}\right) \psi \left(\frac{q}{2\pi}\right) \times \] (20b)

\[ \times \lambda_i(p,q) + (16\psi_0 / \psi^2) \Lambda_1(p,q) + (16\psi_0 / \psi^2) \Lambda_1(p,q) + \ldots \]

\[ T = (\lambda + \mu) \sum B_i \Bigg[ 1 - \frac{1}{2} E \psi \left(\frac{p}{2\pi}\right) \psi \left(\frac{q}{2\pi}\right) \times \] (20c)

\[ \times \lambda_i(p,q) + (16\psi_0 / \psi^2) \Lambda_1(p,q) + (16\psi_0 / \psi^2) \Lambda_1(p,q) + \ldots \]

In the aim of making the equations simpler, the following abbreviations are introduced:

\[ \sigma(x) = \sigma(x) - x / E(x), \quad \chi(x) = E(x) / \sigma(x) \] (18)

while \( \Lambda \) and \( Z \) functions are in non-dimensional form:

\[ \Lambda_0(p,q) = \frac{1}{(p/2\pi)^2 + (q/2\pi)^2} \] (19a)

\[ \Lambda_1(p,q) = \frac{1}{(p/2\pi)^2 + (q/2\pi)^2} \Lambda_0(p,q) \] (19b)

\[ \Lambda_2(p,q) = \frac{1}{(p/2\pi)^2 + (q/2\pi)^2} \Lambda_0(p,q) \] (19c)

\[ \Lambda_3(p,q) = \frac{1}{(p/2\pi)^2 + (q/2\pi)^2} \Lambda_0(p,q) \] (19d)

\[ \Lambda_4(p,q) = \frac{1}{(p/2\pi)^2 + (q/2\pi)^2} \Lambda_0(p,q) \] (19e)

\[ Z_0(p,q) = \frac{1}{(p/2\pi)^2 + (q/2\pi)^2} \Lambda_0(p,q) \] (20a)
A double Fourier series is used to represent buckled profiles of the two chosen types of plates (22-23). These series satisfy all boundary conditions, term by term, and, as it has been previously shown [4-5], are capable of representing any possible buckled profiles for very wide range of aspect ratios and load cases.

### 2.3.1. The adopted deflection series

In order to guarantee the accuracy, the double Fourier series are used to represent buckled profiles of the two chosen types of plates (22-23). These series satisfy all boundary conditions, term by term, and, as it has been previously shown [4-5], are capable of representing any possible buckled profiles for very wide range of aspect ratios and load cases.

Patching loading - analytical approach to critical load determination

Case 1
edges x = ± a/2 simply supported (S)
edges y = ± b/2 simply supported (S)

\[
\begin{align*}
    w & = \sum_{m,n} W_{mn} \left( \frac{m-1}{a} \right) \sin \left( \frac{m \pi x}{a} \right) \sin \left( \frac{n \pi y}{b} \right) \\
    \text{Case 2} & \begin{align*}
        \text{edges x = ± a/2 clamped (C)} \\
        \text{edges y = ± b/2 simply supported (S)}
    \end{align*}
\]

\[
\begin{align*}
    w & = \sum_{m,n} W_{mn} \left( \frac{m-1}{a} \right) \sin \left( \frac{m \pi x}{a} \right) \sin \left( \frac{n \pi y}{b} \right)
\end{align*}
\]

2.3.2. Strain energy due to bending

During the evaluation of the total potential energy of the plate, the first step is defining the strain energy due to plate bending in the traditional way

\[
U = \frac{1}{2} D \int_{a}^{b} \int_{b}^{a} \left( \frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2} \right)^2 - 2(1-v) \left( \frac{\partial^2 w}{\partial x \partial y} \right)^2 \, dx \, dy
\]

where D is flexural rigidity of the plate.

The part of the potential energy of the plate associated with the work done by external loads is presented by the expression (25). In this expression, the stresses within the plate \( N_x , N_y \) and \( T_z \) are given by equations (21) that represent solutions of the Mathieu’s exact approach:

\[
V = - \frac{t}{2} \int_{a}^{b} \int_{a}^{b} \left( \frac{\partial^2 w}{\partial x \partial y} \right)^2 + 2T_z \frac{\partial w}{\partial y} \left( \frac{\partial w}{\partial y} \right) + 2T_z \omega \frac{\partial \omega}{\partial y} \right) \, dx \, dy
\]

2.3.3. Formulation of eigenvalue problem

Finally, after the definition of the strain energy of the plate bending \( U \), and of the value which responds to the work done by external forces \( V \), the total potential energy of the system can be written in form:

\[
\Pi = U + V
\]

From the minimum potential energy principle, the condition (27) is given by

\[
\frac{\partial \Pi}{\partial W_{mn}} = 0
\]

which basically represents linear system of \( m \cdot n \) homogenous equations per unknown coefficients \( W_{mn} \). The existence of nontrivial solution, expressed through condition that the determinant of the system is equal to zero, leads to the solution of the classical eigenvalue problem. In its scope, the lowest value has the only practical importance, which presents the requested critical load. Surely, the usage of the corresponding software (MATHEMATICA) was necessary in the solving process because of the complexity of the analytical procedure. The complexity directly depends on the adopted number of terms of the stress functions, as well as of number of terms of the deflection functions.

3. Numerical examples and results

For the case of patch-loading analyzed by model 1, all results for buckling load coefficients for two type of plates with different boundary conditions (SSSS and CSCS), calculated for plate aspect ratios between \( \phi = 0.3 - 1 \) and different load...
distributions $\gamma = 0.1 \rightarrow 1$, are presented in Tables 2 and 3. On the other hand, critical loads obtained by model 2 are presented in the chart form (Figure 9.a and 9.b) to enable easy comparison between results of two patch loading models (Figure 8.). In these tables for the model 1, there are not only buckling coefficients obtained by analytical approach, but also there are, as some kind of “experimental” values, the results of finite element method (ANSYS).

It is important to point out that when it comes to analytical solutions in the form of infinite series, convergence control is required. Namely, from the practical reasons it was necessary to include some limits regarding number of series terms for stress as well as for deflection functions. Because of that limitation, every proposed analytical approach to critical load determination required thorough convergence control. From the stress function point of view, for the load types DEA and DEB, accuracy of the solution is achieved with 40 and more terms. In the case of the deflection function, sometimes it is desirable the presence of more number of terms in dependence on boundary conditions and types of the load. For initial patch loading models with two different types of boundary conditions (SSSS and CSCS) analyzed in this paper, deflection functions with 20 terms (22-23) were absolutely capable to describe deformed shape for any plate $f$ or load $g$ aspect ratio.

Certainly, we are aware of the fact we get the solution little bit higher than exact one, by limiting the numbers of terms. However, analyzing results from Tables 2 and 3, obtained

4. Analysis of the results of calculations

With the detailed analysis of the presented results for model 1 (Tables 2 and 3), it is very easy to notice very good behavior of analytical solution for both types of boundary conditions in the complete considered ranges of the plate ($\phi = 0.3 - 1$) and load ($\gamma = 0.1 - 1$) aspect ratios. Tables 2 and 3, which present values of buckling coefficients of two types of plates (SSSS, CSCS) under patch loading defined with model 1, refer to the maximal discrepancy of 0.25% (CSCS $\phi = 0.3$ and $\gamma = 1$) in relation to the results evaluated by the application of the finite element method.

It is important to point out that for the problems regarding stability of the plates, buckling coefficients obtained by finite element method are below exact values, as a result of limited number of terms in interpolation functions. Knowing that, small existing discrepancy between presented results confirms accuracy of the analytical approach.

Results obtained with model 2 were subjected to the same type of control. Comparison with finite element method solutions (ANSYS) confirms high level of concordance for all load and plate types (maximal discrepancy for the simply supported plate SSSS is 0.3%, for the case of $\phi = 0.1$ and $\gamma = 1$; maximal discrepancy for the clamped plate CSCS is 0.95% for the same case of $\phi = 0.1$ and $\gamma = 1$). The reason why results for model 2 are presented in the chart form instead of table form is because of a slight deviation from model 1 and better models comparison (Figure 9).
From the chart, it is obvious that in the case of simply supported plate (Figure 9a) maximal discrepancy between two models is in the range -0.9% ($\gamma = 0.1$) and 1.5% ($\gamma = 1$) for aspect ratio $\phi = 0.3$. In all other cases regarding plate SSSS discrepancy in buckling load for two models are within 1%. In the case of plate with two clamped edges CSCS, some discrepancy was expected, especially for the category of wide strips ($\phi = 0.3$ and $\phi = 0.5$). Figure 9.b point out that results for model 2 are slightly below corresponding values calculated for the model 1 (up to 6% for $\phi = 0.3$ and $\gamma = 1$). However, for nearly square plates, in all load range, discrepancy is within 0.1%. As a final conclusion we can point out that two models have very similar behavior under patch loading which results in very similar, almost identical buckling coefficients.

Since in this paper the behavior of plates with simply supported and clamped edges is investigated, it was considered interesting to analyze increase in buckling capacity due to different boundary conditions (SSSS and CSCS). For the load case $\gamma = 0.3$ (Figure 10.), the difference between values of critical load for simply supported and clamped plates is, especially for category of wide strips, up to 2.8 times (for plate SSSS with aspect ratio $\phi = 0.3$ coefficient is $K_2 = 0.8809$ while for plate CSCS is $K_2 = 2.4361$). For the full load range increase is in-between 1.7 and 2.8 times.

5. Conclusion

At the end, the main conclusion can be that obtained exact stress functions, as well as adopted deflection functions, for the two initial mathematical models, are capable to describe the behavior of the plates under patch loading and produce very accurate solutions. Now it is possible to go a step further and build new, more advanced models, by introducing shear stresses along the shorter plate edges and/or shear effects on the flange-web junction. Until now, such effect has never been discussed analytically.
