The Influence of Agroclimatic Factors on Soil CO$_2$ Emissions

Darija Bilandžija, Željka Zgorelec and Ivica Kisić

University of Zagreb, Faculty of Agriculture, Department of General Agronomy, Zagreb, Croatia

**ABSTRACT**

There has been a significant increase of atmospheric greenhouse gas (GHG) concentrations since industrial revolution till nowadays. Approximately 10% of total GHG emissions in Croatia belong to the agricultural sector. In this sector, one part of CO$_2$ is released from soil by soil respiration (soil CO$_2$ efflux). Due to these facts, it is of scientists’ interest to determine the influence of tillage treatments on soil CO$_2$ efflux and to determine a relationship between tillage induced CO$_2$ emissions and climatic factors. Field experiment with six different tillage treatments was set up on Stagnic Luvisols near Daruvar (central lowland Croatia). Tillage treatments were: black fallow (BF), ploughing up and down the slope to 30 cm (PUDS), no – tillage (NT), ploughing up and down slope to 30 cm (PAS), very deep ploughing across the slope to 50 cm (VDPAS) and subsoiling across the slope to 50 cm (SSPAS). Soil CO$_2$ efflux was measured using closed static chamber method to quantify soil CO$_2$ efflux during 2012 ($n=13$) when cover crop was corn. Tillage had a significant effect on CO$_2$ efflux. The lowest average CO$_2$ efflux was determined at the BF treatment with the average CO$_2$ efflux of 29.4 kg ha$^{-1}$ day$^{-1}$. Comparing the treatments with the cover crop, the highest average CO$_2$ efflux was determined at the NT treatment followed by SSPAS, VDPAS, PAS and PUDS treatment with the average CO$_2$ efflux of 90.9 kg ha$^{-1}$ day$^{-1}$, 83.5 kg ha$^{-1}$ day$^{-1}$, 68.9 kg ha$^{-1}$ day$^{-1}$, 66.7 kg ha$^{-1}$ day$^{-1}$, 56.0 kg ha$^{-1}$ day$^{-1}$ respectively. Average CO$_2$ effluxes were moderate positively correlated with soil temperatures at 10 cm depth ($r=0.42$), moderate positively correlated with air temperature ($r=0.45$), and non correlated with soil moisture content at 10 cm depth ($r=0.08$), while strong negatively correlated with relative air humidity ($r=0.55$). The CO$_2$ efflux was higher during the second half of spring and in the first half of summer while lower CO$_2$ efflux was determined during the period autumn – winter CO$_2$ effluxes were higher in first half of corn growing season than in the second half of corn growing season and the period without the cover crop. Our study suggests that tillage practices have significant influence on soil CO$_2$ emissions.

**Key words:** CO$_2$ efflux, agricultural soil, soil temperature, soil moisture, air temperature, relative air humidity, soil tillage

**Introduction**

Climate change is one of the greatest challenges that the world is facing today. Since the industrial revolution till nowadays, there has been a significant increase of atmospheric greenhouse gas (GHG) concentrations. The impact of climate change is obvious in all parts of the world as well as in the Croatia. In the Republic of Croatia, the period 1991–2000 was the warmest decade of the 20th century and it is predicted that average temperatures in 2025 will increase by maximum of 1 °C in winter, summer and autumn, while spring temperatures will remain the same. To reduce the global GHG emissions, Kyoto protocol has been adopted in Kyoto in 1997 and Republic of Croatia has ratified the Kyoto protocol in 2007. According to Kyoto protocol, countries have to report on their GHG emissions from six sectors and one of them is agricultural sector. Approximately 10% of total GHG emissions in Croatia belong to the agricultural sector according to experts’ estimates.

Among GHGs, carbon dioxide (CO$_2$) is one of the most significant contributors to regional and global warming. One part of CO$_2$ is released from soil in the process of soil respiration. Soil respiration or soil CO$_2$ efflux is one of the most important components of the ecosystem carbon budget, which consists of organic matter decomposition and mineralization, root respiration and rhizosphere or

Received for publication November 29, 2013
faunal respiration. Soil–plant system and the pedosphere-atmosphere interface are sites of intense carbon exchange with 10% of atmospheric carbon passing through soils annually. Moreover, soil contains twice the amount of carbon as the atmosphere and it is therefore an important component of the global carbon budget.

Studies have shown that factors such as soil temperature, soil moisture content, tillage systems, irrigation practices, presence of organic matter and nutrients, soil aeration, microbial processes and soil diffusivity influence the CO₂ production and emission rates from the soil surface. Tillage and soil disturbance strongly affect CO₂ emission by creating soil conditions favourable for oxidation and mineralization of organic C in the soil. Tillage accelerates soil CO₂ emission by improving soil aeration, soil disaggregation and increasing the contact between soil and crop residue. Also, land management practices can influence soil temperature and moisture content which can directly affect CO₂ effluxes from the soil surface. Soil temperature and soil moisture content are the characteristics that most commonly impact temporal variation in CO₂ efflux from soils. An increase in soil temperature accelerates organic matter decomposition, oxidation, microbial and root activity, and C mineralization processes. This acceleration thereby increases CO₂ emission from the soil and thus the soil temperature is an important factor in controlling major processes in the C cycle. Soil moisture content is another important factor affecting biological respiration and soil CO₂ evolution. Soil moisture also affects CO₂ production and distribution through its influence on gas diffusion and microbial activity. Therefore, measuring soil CO₂ efflux is crucial to accurately evaluate the effect of soil management practices on global warming and carbon cycling. Although many studies on soil CO₂ emissions are conducted around the world, the lack of research and scientific data on the soil CO₂ emissions in the Republic of Croatia has motivate us to begin the research on the influence of agroclimatic factors on soil CO₂ emissions.

**Material and Methods**

**Experimental site and tillage treatments**

Field experiment with six different tillage treatments usually implemented in Croatia was set up in Biogradovac near Daruvar (elevation: 133 m asl; N 45° 33' 937'', E 17° 02' 056'') in central, lowland Croatia. Field experiment was established in 1994 with the aim of investigation on determination of soil degradation by water erosion and later, in 2011, expanded to the research on soil CO₂ concentration measurements. Soil type at the experimental site is determined as Stagnic Luvisols. Tillage treatments differed in tools that were used, depth and direction of tillage and planting. Size of each tillage treatment is 22.1 m × 1.87 m. Tillage treatments were:

1. BF: black fallow, control treatment – ploughing direction is up and down the slope;
2. PUDS: ploughing to 30 cm – ploughing and planting direction is up and down the slope, disked and harrowed;
3. NT: no-tillage – planting in conducted directly into the mulch with planting direction up and down the slope;
4. PAS: ploughing to 30 cm – ploughing and planting direction is across the slope, disked and harrowed;
5. VDPAS: very deep ploughing to 50 cm – ploughing and planting direction is across the slope, disked and harrowed;
6. SSPAS: ploughing to 30 cm plus subsoiling to 50 cm – ploughing, subsoiling and planting direction is across the slope, disked and harrowed.

**Research period, climate conditions and cover crop at the experimental site**

The measurements of soil CO₂ concentrations and agroclimatic conditions were conducted during the year 2012 (n=13), approximately once per month. All measurements were conducted in three repetitions what makes the total number of 234 measurements for each parameter (13 measurement dates × 3 repetitions × 6 treatments).

For the interpretation of climate conditions in the climatological period 1961–1990 and studied 2012 at the experimental site, the official meteorological data from the main meteorological station of Meteorological and Hydrological Service of Croatia located in Daruvar were used. The climate conditions at the experimental site are described by Lang’s rain factor and Walter climate diagram. Lang’s rain factor represents the ratio of mean annual precipitation amount (mm) and mean annual temperature (°C). The climate classification for the interpretation of Lang’s rain factor is conducted according to Gračanin’s climate classification.

Cover crop at the experimental field was corn (Zea mays L. – hybrid Zlatko), the main arable crop (34.2% of total arable land and gardens area) in Croatia. At the experimental field, corn was seeded on 30 April 2012 and harvest was conducted on 1 October 2012. Depth of sowing was 3-4 cm, distance between rows was 70 cm and inter-row distance was 22 cm, what makes the total number of 65,000 plants per hectare.

**Measurement of agroclimatic factors**

The aim of the research requires the reliable data on the weather conditions, especially on air temperature and relative air humidity. Therefore, at the beginning and the end (about 3 hours later) of each measurement date, the air temperature (°C) and relative air humidity (%) were determined with the adequate instrument (Testo 511, 2011) at the height about 1 m above the soil surface. The research aim also requires the data on the soil temperature and soil moisture in the upper soil layer (at 10 cm depth). Soil temperature (°C) and soil moisture (%) were determined with adequate instrument (IMKO HD2 – probe Trime, Pico64, 2011) at the 10 cm depth in the vicinity of the chambers on each measurement date.
Measurement of CO₂ concentrations

For the measurement of soil carbon dioxide concentrations, the closed static chamber method was used. The chambers are made of lightproof metal material to avoid the sunlight effect on the measurements, and they consist of two parts: frames and caps. The circular frames (25 cm in diameter) are inserted between the growing plants about 5 cm into the soil at the beginning of measurements. The caps are 25 cm in diameter and 9 cm high, fitted with a gas sampling port. Before the chambers closure, the initial CO₂ concentrations inside the frames near soil surface were measured. Afterwards, the chambers were closed with caps and the incubation period was 30 minutes after which the CO₂ concentrations in closed static chambers were measured. In situ measurements of carbon dioxide concentrations (ppm) in the chambers were conducted with portable infrared carbon dioxide detector (GasAlertMicro5 IR, 2011). Measurements were conducted on bare soil and when necessary (at the no-tillage treatment), vegetation was removed from frames inside before the beginning of measurements.

Measurements of carbon dioxide concentrations were conducted in three repetitions at each treatment. The soil carbon dioxide efflux (expressed as kg CO₂ per ha per day) was afterwards calculated according to authors15,16 as:

$$F_{\text{CO}_2} = \frac{[M \times P \times V \times (c_2 - c_1)]}{[R \times T \times A \times (t_2 - t_1)]}$$

Where:
- $F_{\text{CO}_2}$ – soil CO₂ efflux (kg ha⁻¹ day⁻¹)
- $M$ – molar mass of the CO₂ (kg mol⁻¹)
- $P$ – air pressure (Pa)
- $V$ – chamber volume (m³)
- $c_2 - c_1$ – CO₂ concentration increase rate in the chamber during incubation period (μmol mol⁻¹)
- $R$ – gas constant (J mol⁻¹ K⁻¹)
- $T$ – air temperature (K)
- $A$ – chamber surface (m²)
- $t_2 - t_1$ – incubation period (day)

Data analysis

Soil CO₂ efflux, soil temperature, soil moisture, air temperature and relative air humidity were analyzed using SAS according to the GLM procedure in the SAS system package version 8.0017. A linear regression procedure was used to determine the dependence of each air and soil property on soil surface CO₂ efflux. The interpretation of correlation coefficients was conducted according18.

Results and Discussion

Climate conditions at the experimental site

The experimental field is characterised by continental climate. In the largest part of central lowland Croatia there is a prevalent humid climate19. Mean annual amount of precipitation in Daruvar during referent 30-year period (1961–1990) was 787 mm and mean annual temperature was 10.6 °C. According to the Lang’s rain factor (Lf), the 30-year period (1961–1990) was characterised by the humid climate (Lf=83). The year 2012 was dryer and warmer compared to referent period with mean annual precipitation amount of 789 mm and mean annual temperature of 11.8 °C. According to the Lang’s rain factor, the year 2012 was characterised by semihumid climate (Lf=67). In 2012 March and August were drier, and September and December wetter in relation to the reference period (Figure 1). During 2012, summer months June, July and August as well as November were warmer and February colder than the referent period (Figure 2).

Agroclimatic factors and CO₂ efflux

Tillage had a significant effect on CO₂ efflux (Table 1). The same conclusions were obtained by other authors8. The lowest average CO₂ efflux was determined at the BF treatment with the average CO₂ efflux of 29.4 kg ha⁻¹
This data are in accordance with the literature sources that stated that the presence of crops have influence on CO2 emissions and these emission from soil are approximately 2 to 3 times higher in cropped soil compared to bare soil\footnote{20}. If we compare the treatments with the cover crop, the highest average CO2 efflux was determined at the NT treatment followed by SSPAS, VDPAS, PAS and PUDS treatment with the average CO2 effluxes of 90.9 kg ha\(^{-1}\) day\(^{-1}\), 83.5 kg ha\(^{-1}\) day\(^{-1}\), 66.7 kg ha\(^{-1}\) day\(^{-1}\), 66.7 kg ha\(^{-1}\) day\(^{-1}\), 56.0 kg ha\(^{-1}\) day\(^{-1}\) respectively. The higher CO2 emissions under NT could be attributed to maintenance of higher soil water content at the soil surface and higher biological activity. A review of the literature indicates a contradictory results regard to tillage effects on CO2 emissions. The greater average CO2 fluxes were determined under no tillage than under conventional tillage\footnote{21,22} while, in contrast, lower CO2 emissions were observed under no tillage compared to conventional tillage\footnote{7,8,23,24}.

On the measurement dates at the experimental site, the mean (n=13) air temperature was 26.4 °C and mean relative air humidity was 42%. The average soil temperatures differ by maximum of 2.6 °C (Table 1). The highest average soil temperature was determined under VDPAS and the lowest one under the PUDS treatment. Average soil temperatures at the treatments were lower than mean air temperature during the studied period. Furthermore, average soil moisture contents differ by maximum of 2.9% (Table 1). The highest average soil moisture content was determined under NT and the lowest one under the SSPAS treatment which may be attributed to the presence of crop residues on the soil surface under NT which minimizes the losses due to evaporation and surface runoff.

The treatment with the highest average CO2 efflux variation during the investigated period was NT, followed by SSPAS, VDPAS, PAS and BF where CO2 efflux range amounted 212.6 kg ha\(^{-1}\) day\(^{-1}\), 208.3 kg ha\(^{-1}\) day\(^{-1}\), 147.0 kg ha\(^{-1}\) day\(^{-1}\), 135.5 kg ha\(^{-1}\) day\(^{-1}\), 119.9 kg ha\(^{-1}\) day\(^{-1}\) and 74.2 kg ha\(^{-1}\) day\(^{-1}\) respectively (Table 2).

The highest variation of soil temperature was determined at the VDPAS followed by NT, SSPAS, PAS, BF, PUDS with soil temperature range of 39.2 °C, 36.8 °C, 35.0 °C, 34.1 °C, 32.7 °C and 29.9 °C respectively (Table 2).
The treatment with the highest variation of soil moisture content during the investigated period was PUDS followed by BF, SSPAS, NT, PAS and VDPAS with soil moisture range of 30.7%, 29.8%, 29.2%, 28.6%, 25.8% and 23.6% respectively (Table 2).

The CO₂ efflux was higher during the second half of spring and in the first half of summer while lower CO₂ efflux was determined during period autumn-winter (Figure 5). Higher CO₂ emissions were determined during the summer period and the lowest one in autumn period by other authors. Effluxes of carbon dioxide were related to crop growth. CO₂ effluxes were higher in first half of corn growing season and lower in the second half of corn growing season and period without the cover crop what was likely a result of considerable contributions from root and microbial respiration. Other authors also determined that CO₂ efflux from soil is closely correlated to plant growth. Higher effluxes determined shortly after the harvest were most likely related to crop root and residue decomposition.

**Relationships between CO₂ efflux, air and soil properties**

Correlation between CO₂ efflux, air and soil properties are presented at Figures 6–9. Average CO₂ effluxes were moderate positively correlated with soil temperatures at 10 cm depth ($r = 0.42$), moderate positively correlated with air temperature ($r = 0.45$), and non correlated with soil moisture content at 10 cm depth ($r = 0.08$), while strong negatively correlated with relative air humidity.
Comparing the treatments with the cover crop, the high-water content \( (r=0.75) \) and soil temperatures in the top 20 cm \( (r=0.87) \) and negatively with soil water content \( (r=0.75) \). Other authors have also reported positive correlation between CO2 fluxes and soil temperature,6,7,27,28. An increase of CO2 effluxes with the increase of soil moisture content can be attributed to the fact that sufficient soil moisture content stimulates microbial activity and enhances root respiration, thereby increasing CO2 emission from the soil surface. A direct linear relationship was determined between volumetric soil moisture content and CO2 efflux6 while authors29 concluded that CO2 emissions are primarily depended on temperature, but becomes moisture dependent as soil dries.

**Conclusions**

This research was initiated to assess the CO2 effluxes on Stagnic Luvisols that has been managed using BF, PUDS, NT, PAS, VDPAS and SSPAS practices for 16 years. The experimental field is characterised by continental climate. The studied 2012 year was dryer and warmer compared to 30-year period (1961–1990) with mean annual precipitation amount of 799 mm and mean annual temperature of 11.8 °C. In 2012, water deficit in March, July and August was determined. Tillage had a significant effect on CO2 efflux. The lowest CO2 efflux was determined at the BF treatment with the average CO2 efflux of 29.4 kg ha\(^{-1}\) day\(^{-1}\). Comparing the treatments with the cover crop, the highest average CO2 efflux was determined at the NT treatment followed by SSPAS, VDPAS, PAS and PUDS treatment.

**REFERENCES**

(r=0.55). These results are suggesting an increase of CO2 efflux with increase of soil temperature what is attributed to higher soil biological activity. In another study it was determined that CO2 fluxes were positively correlated with air temperatures \( (r=0.8) \) and soil temperatures in the top 20 cm \( (r=0.87) \) and negatively with soil water content \( (r=0.75) \). At the time of measurements, mean \( (n=13) \) air temperature was 26.4 °C and mean relative air humidity was 42% at the experimental site. The average soil temperatures differ by maximum of 2.6 °C. Average soil temperatures at the treatments were lower than mean air temperature during the studied period. Furthermore, average soil moisture content differs by maximum of 2.9%.

The treatment with the highest variation of CO2 efflux during the investigated period was NT (212.6 kg ha\(^{-1}\) day\(^{-1}\)) and the treatment with the lowest variation of CO2 efflux was BF (74.2 kg ha\(^{-1}\) day\(^{-1}\)). The highest variation of soil temperature was determined at VDPAS (39.2 °C) treatment and the lowest one was determined at PUDS (29.9 °C) treatment. The treatment with the highest variation of soil moisture content was PUDS (30.6%) and the treatment with the lowest variation of soil moisture content was VDPAS (23.6%).

The CO2 efflux was higher during the second half of spring and in the first half of summer while lower CO2 efflux was determined during period autumn-winter. CO2 effluxes were depended on crop growth and they were higher in the first half of corn growing season and lower in the second half of corn growing season and the period without the cover crop.

Average CO2 effluxes were moderate positively correlated with soil temperatures at 10 cm depth \( (r=0.42) \), moderate positively correlated with air temperature \( (r=0.45) \), and non correlated with soil moisture content at 10 cm depth \( (r=0.08) \), while strong negatively correlated with relative air humidity \( (r=0.55) \). Our study suggests that tillage practices have a significant influence on soil CO2 emissions.
Od početka industrijske revolucije do danas, značajno se povećala koncentracija stakleničkih plinova u atmosferi. Približno 10% od ukupnih emisija stakleničkih plinova u RH pripada sektoru poljoprivrede. U tom sektoru, dio CO₂ se otpušta iz tla putem disanja tla (CO₂ flukse iz tla). Temeljem navedenog, znanstvenicima je od interesa utvrditi utjecaj načina obrade tla na flukse CO₂ iz poljoprivrednih tala te utvrditi odnos između obradom uzrokovanih emisija CO₂ i klimatskih čimbenika. Pokusno polje sa četiri različita načina obrade tla postavljeno je na pseudogleju distričnom kod Daruvara (središnja nizinska Hrvatska). Načini obrade tla su: crni ugar (BF), oranje do 30 cm uz i niz nagib (PUDS), izostavljen obrada (NT), oranje do 30 cm okomito na nagib (PAS), vrlo duboko oranje do 50 cm okomito na nagib (VDPAS) te podrivanje do 50 cm okomito na nagib (SSPAS). CO₂ flukse iz tla se mjerio metodom zatvorenih staklenih komora tijekom 2012 (n=13) kada je pokrovni usjev bio kukuruz. Načini obrade su imali značajan utjecaj na CO₂ flukse iz tla. Najniži prosječni CO₂ flukse su utvrđeni na varijanti BF gdje je prosječan CO₂ fluksu iznosio 29,4 kg ha⁻¹ day⁻¹. Usporedivi varijante sa usjevom, najviši prosječan CO₂ fluksu je utvrđen na varijanti NT (90,9 kg ha⁻¹ day⁻¹) nakon koje su slijedile varijante SSPAS (83,5 kg ha⁻¹ day⁻¹), VDPAS (68,9 kg ha⁻¹ day⁻¹), PAS (66,7 kg ha⁻¹ day⁻¹) i PUDS (56,0 kg ha⁻¹ day⁻¹). Prosječni CO₂ fluksevi su prema jačini korelacije bili srednje pozitivno korelirani sa temperaturama tla na 10 cm dubine (r=0,42), srednje pozitivno korelirani sa temperaturama zraka (r=0,45), sa vlago tla na 10 cm dubine (r=0,08) dok je utvrđena jaka negativna korelacija sa relativnom vlago tla r (r=0,55). CO₂ flukse je bio viši tijekom prve polovice vegetacijskog perioda kukuruza u odnosu na drugu polovicu vegetacijskog perioda kukuruza i perioda bez usjeva. Naša istraživanja upućuju da su načini obrade tla imali značaj utjecaj na emisiju CO₂ iz tla te da je temperatura tla bila glavni faktor utjecaja na CO₂ emisiju iz tla.
