THE INFLUENCE OF INK CONCENTRATION AND LAYER THICKNESS ON YELLOW COLOUR REPRODUCTION IN LIQUID ELECTROPHOTOGRAPHY TONER

Igor Majnarić, Aleš Hladnik, Tadeja Muck, Ivana Bolanča Mirković

In liquid toner electrophotography, colour gamut is often diminished in the yellow region leading to problems with photo quality prints. It is known that the concentration of pigment particles in the printing ink and its thickness when applied on a paper substrate decisively influence final print quality. Variation of these two parameters for the yellow process ink was performed by modifying the printing process of the electrophotographic printer HP Indigo S1000. Printed colour patches of ECI test chart were analysed colorimetrically and using image analysis approach. Two-way analysis of variance was implemented to statistically assess the obtained results. Both studied responses – colour gamut volume and area coverage of halftone dots – were found to be primarily influenced by the yellow ink layer thickness and much less by the ink concentration. Increase from one to two ink layers had a significantly stronger effect on each of the two responses when compared to an additional increase from two to three layers.

Keywords: colour gamut; colour reproduction; halftone dots; liquid toner electrophotography; print quality; tone value

1 Introduction

In obtaining a high-quality colour reproduction, process printing inks (CMYK) and especially their colorants – pigments or dyes – play a decisive role. Ink formulation and the amount of ink being used must meet the requirements of the actual printing technology. In particular, concentration of pigment particles in the yellow ink as well as the final layer thickness of the ink applied to the printing substrate can be varied by a printer to assure the desired reproduction of lighter tones.

The aim of this study was to examine the technological possibilities and limitations related to the use of the yellow process ink within the electrophotographic printing system with the liquid toner – also known as HP ElectroInk. The results should also provide some directions on how to improve the reproduction of yellow colour, obtain higher colour saturation, and consequently, to achieve higher print quality with larger colour gamut.

During the printing process, to attain a larger colour gamut it is common to apply a higher amount of the colorant onto the printing substrate. Technically, this can be accomplished in one of two ways: either by increasing the concentration of the pigmented toner particles in ink or by increasing the number of ink layers.

2 Liquid electrophotography toner

The development process in the liquid toner electrophotography is very complicated and consists of several consecutive steps [1]. The final ink layer thickness is primarily influenced by the voltages of the developer drum and the developer rollers. By varying individual voltages, higher colour saturation in prints can be obtained [2].

ElectroInk contains charged pigmented toner particles in a liquid carrier. Similarly to other digital printing technologies, such as dry electrophotography, printing is performed via electrically controlling the location of the toner particles. In its basic state the ink is an emulsion consisting of pigments in a form of a thermal polymer (24-29%), which is dispersed in a non-polar volatile oil (70-75%). The ink also contains additives for increasing the conductivity (about 10 %) [3]. ElectroInk is supplied as a concentrated paste that is loaded into the press in tubular cartridges. Inside the press it is fed into ink supply tanks and diluted with oil, to form a fluid mixture ready for printing.

During the printing process, the ElectroInk structure rapidly alters. Ink viscosity increases due to a high temperature (θ = 125 °C) and loss of the volatile solvent. By heating the thermal polymer, the process of plasticity begins causing the polymer to become suitable for adhering to the printing substrate [4].

Particles of the yellow thermal toner have a characteristic fluffy shape with the size ranging from 1 to 5 µm [5, 6]. Such a shape serves primarily to ease the binding of the conductivity-increasing additives. These polar additives adhere to the pigmented toner particles with their positively charged molecular groups. The particles are then ready to move towards a more positive electrostatic field, i.e. a field with a lower negative charge [7, 8, 9].

Further ink film thickness increase on the printing substrate is possible by means of an overprinting. Such a

I. Majnarić et al.

The possibility exists only with satellite electrophotographic machines in which one printing unit is used for printing several inks [10, 11, 12, 13]. In this case the printing is done on the already printed (dried) ink layer.

3 Experimental part

For the experiment we used ECI test chart (target) with 378 colour patches. The chart was printed with the electrophotographic machine HP Indigo S1000 (resolution: 812 × 812 dpi). The printer normally uses four process inks (CMYK) of which the yellow one was modified for the purpose of our study. This (Yellow 74) is an azo-based compound (Dalamar yellow C. I. 11741) with the chemical formula C_{18}H_{18}N_{4}O_{6}. The printing substrate was a calandered paper with the grammage of 280 g/m².

By adding various amounts of the pigment, three yellow ink concentrations (C) were prepared – C1=1.28; C2=1.61 and C3=1.98 – characterized by different ink densities as measured by the portable ink density meter EAS-1120-53 that was developed by HP Indigo. In addition, the repetition of individual yellow colour separations was accomplished. In this way YMCK (with one yellow layer; L1), YYMCK (with two yellow layers; L2) and YYYMCK prints (with three yellow layers; L3) were made. Consequently, nine different combinations of yellow ink concentration-ink layer thickness were investigated as schematically displayed in Fig. 1.

By adding various amounts of the pigment, three yellow ink concentrations (C) were prepared – C1=1.28; C2=1.61 and C3=1.98 – characterized by different ink densities as measured by the portable ink density meter EAS-1120-53 that was developed by HP Indigo. In addition, the repetition of individual yellow colour separations was accomplished. In this way YMCK (with one yellow layer; L1), YYMCK (with two yellow layers; L2) and YYYMCK prints (with three yellow layers; L3) were made. Consequently, nine different combinations of yellow ink concentration-ink layer thickness were investigated as schematically displayed in Fig. 1.

Printed colour patches were examined by spectrophotometer X-rite DTP 20 using 0/45° measuring geometry. The obtained L*a*b* values were used for the calculation of colour differences (CIE LAB delta E2000) and colour gamut volumes (Monaco Profiler Platinum Version). Digital images of the printed halftone dots were obtained by Leica DR 2400 optical microscope with a built-in 1.3 megapixels Dinolite camera. Subsequent image analysis was performed by means of ImageJ software [14, 15, 16]. All major processing steps of our study are presented in Fig. 1.

4 Results and discussion

Colorimetric data for the 378 printed colour patches enabled calculations of colour gamut volumes for each of the nine ink concentration – ink layer thickness combinations. CIE a*b* diagrams for the three typical lightness (L*) values are displayed in Figs. 2 and 3.

**Figure 2** 2D colour gamuts for test chart patches printed with different concentrations and constant number of layers (= two; L2) shown for L*= 20 (top), L*= 50 (middle) and L*= 80 (bottom).
During printing, the simplest control parameter for halftone value transfer is the measurement of the dot percentage in the halftone patches of the ECI test chart. Variation of the two investigated parameters – yellow ink concentration and ink layer thickness – directly affected the appearance and characteristics of the halftone dots and, consequently, caused the tone value increase (dot gain). Yellow halftone patches at 50 % A (tone value) were subsequently analysed. Fig. 4 shows six typical halftone yellow patches at 50 % A.

Yellow halftone patches at 50 % A were further processed using image analysis approach. Each imaged printed patch was converted into a grayscale - and finally into a binary image using intensity thresholding (Otsu's method). Tone value – percentage of area covered by halftone dots – was calculated.

Two-way analysis of variance (ANOVA) results for colour gamut volume and area coverage at the 95 % confidence level are displayed in Tab. 1 and Tab. 2, respectively. Since five measurements were obtained for each of the nine ink concentration – layer thickness combinations, it was also possible to estimate the interaction effect between the two investigated parameters.

5 Conclusions

Our study suggests that a higher colour gamut volume in yellow colour region can be achieved primarily by multilayer printing, i.e. by increasing the number of yellow ink layers – especially from one to two – and much less by raising the concentration of the pigmented toner particles in the yellow ink. Such an increase in layer thickness, however, has a detrimental effect on the characteristics of the printed halftone dots, causing an undesirable tone value increase (dot gain). Multilayer printing increases the dynamic range but at the same time reduces bit depth of a printed image. Therefore, if we want to increase the colour gamut volume and preserve optimal dynamic range, it is recommended to use two layers printing only for reproducing solid yellow tones.

ANOVA results show that both layer thickness and ink concentration have statistically significant effects on color gamut volume at 95 % confidence level. Increasing the values of each of the two parameters results in a larger gamut volume (Fig. 5). Significance of the interaction effect (P-value < 0,05) is almost exclusively due to the extremely large contribution of the first factor – layer thickness. On the other hand, tone value increase (dot gain) is only influenced by the number of yellow ink layers, i.e. layer thickness, while ink concentration has virtually no impact on this dependent variable (Tab. 2 and Fig. 6). It can be noticed that an increase in the number of ink layers from 1 to 2 has a much stronger effect on both dependent variables when compared to the further addition of the third layer (L2 \(\rightarrow\) L3).
