Efficient Implementation for Deterministic Finite Tree Automata Minimization

Younes Guellouma and Hadda Cherroun
Laboratoire LIM, Université Amar Telidji de Laghouat, Laghouat, Algérie

We address the problem of deterministic finite tree automata (DFTA) minimization. We describe a new alternative to implement both standard and incremental tree automata minimization using a well-defined graph representing the automaton to be minimized. We show that the asymptotic complexity of the standard implementation is linearithmic and the incremental one is $O(n \log(n))$ where $n$ is the DFTA size.

Theory of Computation → Design and analysis of algorithms → Mathematical optimization → Discrete optimization
Theory of Computation → Design and analysis of algorithms → Graph algorithms analysis

Keywords: automata theory, minimization, trees, asymptotic complexity

1. Introduction

Tree automata constitute a powerful theoretical tool for several real applications such as XML schemata [1], natural languages processing [2], verification techniques, program analysis etc. In this paper, we focus on the minimization of deterministic finite tree automata (DFTA). In the literature, all the minimization techniques [3], [4], [5] are largely inspired by finite string automata (FSA) minimization which was studied for the first time by Huffman and Moore [6]. Their algorithm was based on the definition of distinguishable pairs of states. At the end of the algorithm, all states judged indistinguishable were merged. Later, Hopcroft [7] defined a new algorithm which proceeds by refining the coarsest partition until no more refinements are possible.

Following the same steps, new minimization techniques for tree automata have emerged. Early in 1967, Brainerd [3] proposed the first DFTA minimization method which we call standard method. Since these several algorithms and implementations have been created, but they all followed the same approach as Brainerd's algorithm like Arbib [4], Gécseg and Steinby [5] and Comon et al. [8].

After that, Watson [9] designed a new minimization method called incremental technique, in which they use a recursive function that decides if two states are equivalent. This method constitutes the basics of many other techniques [10], [11].

Another particular case is the deterministic acyclic tree automata. It was first defined on strings [12]. Next, many other works proposed standard and incremental procedures for this case like in [13].

Concerning complexity, almost all the authors have dedicated large part to complexity study and in many cases. It was maintained by empirical tests and experimental evaluations. In cyclic case, Hopcroft minimization [14] remains the most efficient algorithm known for solving this problem for cyclic automata, the worst-case complexity of this minimization is $O(a \cdot n \cdot \log(n))$ where $a$ is the size of the alphabet and $n$ the number of the states of the automaton to be minimized. For acyclic automata, the minimization can be done in linear time (see [15], [16]).

However, in tree case, the complexity of standard minimization needs a quadratic time. Although the numbers of works and improvements inspired by the standard method like the technique of Carrasco et al. [17], the whole...
asymptotical complexity remains quadratic. However, Abdullah et al. [18] introduced a method in which they adapted Paige-Tarjan algorithm [19] to refine an equivalence relation in order to minimize a non-deterministic automaton (NFTA). Since the deterministic automata is a particular case of non-deterministic automata, the last approach works well for it and gives the best known complexity in tree case which is \(O(m\cdot n)\) where \(m\) is the maximum rank of the alphabet, \(n\) is the size of the automaton and \(n\) is the number of its states (see [20]).

In this paper, we present an efficient implementation of DFA using usual graph properties. We give a general algorithm for the standard minimization and we show that the asymptotic complexity of this construction reaches the best known one which can be deduced by combining Abdullah et al. [18] and Höfgberg et al. [20] work on NFTA. For the second, we extend materials presented in [21] and we detail a new incremental DFA minimization approach. Then we discuss its application in cyclic and acyclic automata. We show that this new algorithm improves the complexity given by [10], [21] and gives a new complexity when dealing with the acyclic case.

The paper is organized as follows. In Section 2, we give some preliminaries and basic properties on DFA. Afterward, we recall the standard algorithm of DFA minimization in Section 3. Then, in Section 4 we present a graph view of a DFA and introduce some usual properties. Moreover, we give a general algorithm for the standard minimization. Finally, Section 5 is allocated to incremental minimization of DFA. We conclude in Section 6.

2. Preliminaries

Given a set of symbols \(\Sigma\) called alphabet, the set of unranked ordered trees \(T\) over \(\Sigma\) is defined inductively as follows: \(\Sigma\) and \(\Sigma^0\) located to incremental minimization of DFTA. Moreover, we give a general algorithm for the standard minimization. Finally, Section 5 is allocated to incremental minimization of DFTA. We conclude in Section 6.

3. Tree Automata Minimization

A deterministic tree automaton can be minimized by removing all its useless states and computing its Nerode equivalence relation [22]. Indeed, the Nerode equivalence reflects states having the same behaviour in terms of tree acceptance. In other words, two states \(p\) and \(q\) are equivalent w.r.t Nerode relation if and only if \(L(p) = L(q)\). Therefore, equivalent states can be safely merged without affecting the accepted language. The computation of this relation can be achieved by means of two different approaches. The first one that we call "standard approach" computes a series of equivalence relations (or partitions) \(\equiv_0, \equiv_1, \ldots\). The relation \(\equiv_0\) is the coarsest one. At each step, the relation \(\equiv_{i+1}\) is obtained by splitting the relation \(\equiv_i\) while respecting that \(\equiv_i\) is coarser than \(\equiv_{i+1}\). This approach seeks to reach a relation gathering all equivalent states that respect minimization in one partition.

The second one called "incremental approach" starts with a singleton partition for each state and iteratively merges partitions that are shown to be equivalent. The process stops when the greatest-fixed-point is reached. Let \(\mathcal{A} = (\Sigma, Q, \Delta, \lambda)\) be a DFTA \(\equiv\) over \(\Sigma\) is an equivalence relation such that \(p \equiv q\) implies:

1. \(p \equiv q\) if and only if \(p \equiv q\) and \(q \equiv p\) if and only if \(p \equiv q\) and \(q \equiv p\).
2. for all \(p \in \bigcup \Sigma^* \times Q^* : \delta(p\epsilon) = \delta(p\lambda)\) for all \(1 \leq \epsilon \leq n\).

Minimization for DFTA was first discussed in the late 1960s by Brainerd [3], and standardised in [8], [17]. It computes the equivalence relation \(\equiv\) by successive approximations \((\equiv_i)_{i \geq 0}\):

1. \(p \equiv_0 q\) if and only if \(p \equiv q\) if and only if \(p \equiv q\).
2. \(p \equiv_i q\) if and only if \(p \equiv j q\) and \(q \equiv k p\) for all \(i \leq j \leq k\).

The computation of the family \(\equiv_i\) can then be done by successive approximations until reaching the stable point.

Lemma 1. For \(k \geq \mid \mathcal{Q} \mid - 2\), we have \(\equiv_{k+1} = \equiv_k\).

To prove this lemma, one has to use the property that each cycle's length cannot exceed \(\mid \mathcal{Q} \mid - 2\) (the number of nodes in one graph).
asymptotical complexity remains quadratic. But, Abdullahs [18] introduced a method in which they adapted Paige-Tarjan algorithm [19] to refine an equivalence relation in order to minimize a non-deterministic automata (NFTA). Since the deterministic automata is a particular case of non-deterministic automata, the last approach works well for it and gives the best known complexity in tree case which is $O(m\cdot \log(n))$  

The set of ranked ordered trees $T_r$ over a ranked alphabet $\Sigma$ is the smallest set satisfying: $p^0 \in T_r$; $x, y \in T_r \Rightarrow xy \in T_r$. A tree language $L$ is a subset of $T_r$. 

The subset of p-ary symbols of $\Sigma$ is $\Sigma_1 = \{\sigma_1, \ldots, \sigma_n\}|p|$. We use the notation $\sigma(t)$, $\sigma_1(t)$, $\ldots$, $\sigma_n(t)$ respectively for constant, unary, binary, ..., p-ary symbols. 

The paper in present an efficient implementation of DFTA using usual graph properties. We give a general algorithm for the standard minimization which is the number of its states (see [20]). 

We conclude in Section 6. 

An alphabet is ranked if there exists a map $\mathcal{A}: \Sigma \rightarrow \mathbb{N}$, called the rank of symbols, such that $\mathcal{A}(\sigma) \geq \mathcal{A}(\rho)$ for all $\sigma, \rho \in \Sigma$ and $\mathcal{A}(\epsilon) = 0$. The subset of $\Sigma$ with rank $\leq r$ is denoted $\Sigma_r$. 

We discuss its application in cyclic and acyclic cases. 

Given a set of symbols $\Sigma$ called alphabet, the set of unranked ordered trees $T_o$ over $\Sigma$ is defined inductively as follows: $\Sigma$ is the smallest set satisfying: $p^0 \in T_o$; $x, y \in T_o \Rightarrow xy \in T_o$. A tree language $L$ is a subset of $T_o$. 

The paper is organized as follows. In Section 2, we give some preliminaries and basic properties on DFTA. Afterward, we recall the standard algorithm of DFTA minimization in Section 3. Then, in Section 4 we present a graph view of DFTA and introduce some useful properties. Moreover, we give a general algorithm for the standard minimization. Finally, Section 5 is allocated to incremental minimization of DFTA. We conclude in Section 6.

### 2. Preliminaries

Given as a set of symbols $\Sigma$ called alphabet, the set of unranked ordered trees $T_o$ over $\Sigma$ is defined inductively as follows: $\Sigma \subseteq T_o$ and $\forall \sigma \in \Sigma$, $t_i, \ldots, t_k \in T_o$, $n \in \mathbb{N}: \sigma(t_i, \ldots, t_k) \in T_o$.

An alphabet is ranked if there exists a mapping $\mathcal{A}: \Sigma \rightarrow \mathbb{N}$ which associates to each symbol an arity representing the "fixed" number of its children in a constructed tree. $\mathcal{A}(\sigma)$ is the maximum rank of the alphabet $\Sigma$ (we use $\mathcal{A}(\sigma)$ is known). A tree set $T_o$ is called "ranked" if and only if: $\forall \sigma(t_i, \ldots, t_k) \in T_o$, $n = \mathcal{A}(\sigma)$.

A tree $t$ is accepted by an automaton $A$ if $t \in \mathcal{L}(A)$. A tree language $L$ is a subset of $T_o$. A DFTA is acyclic (ADFTA) if and only if: $\forall q \in Q$, $t \in \mathcal{L}(q)$ $\Rightarrow \mathcal{L}(t) \subseteq \mathcal{L}(q)$. 

### 3. Tree Automata Minimization

A deterministic tree automaton can be minimized by removing all its useless states and computing its Nerode equivalence relation [22]. Indeed, the Nerode equivalence reflects states having the same behavior in terms of tree acceptance. In other words, two states $p$ and $q$ are equivalent w.r.t. Nerode relation if and only if $L(p) = L(q)$. Therefore, equivalent states can be safely merged without affecting the accepted language. The computation of this relation can be achieved by means of two different approaches. The first one that we call "standard approach" computes a series of equivalence relations (or partitions) $\equiv_0, \ldots, \equiv_n$. The relation $\equiv_0$ is the coarsest one. At each step, the relation $\equiv_j$, $j > 0$, is obtained by splitting the relation $\equiv_{j-1}$ while respecting that $\equiv_{j-1}$ is coarser than $\equiv_j$. This approach seeks to reach a relation gathering all equivalent states that respect minimization in one partition. The second one called "incremental approach" starts with a singleton partition for each state and iteratively merges partitions that are shown to be equivalent. The process stops when the greatest fixed-point is reached.

Let $A = (Q, \Sigma, Q_0, \Delta)$ be a DFTA, $\equiv$ over $Q$ is an equivalence relation such that $p \equiv q$ implies:

1. $p \in Q \Rightarrow q \in Q$.
2. for all $p \in Q$, $\forall \sigma \in \Sigma: \delta(p, \sigma) \equiv \delta(q, \sigma)$ for all $1 \leq i \leq n$.

Minimization for DFTA was first discussed in the late 1960s by Brainerd [3], and standardised in [8, 17]. It computes the equivalence relation $\equiv$ by successive approximations $(\equiv_{j+1})_{j \geq 0}$:

1. $p \equiv_0 q$ if and only if $(p \in Q \Rightarrow q \in Q)$.
2. $p \equiv_{j+1} q$ if and only if $(p \equiv_q q$ and for all $\forall \sigma \in \Sigma: \delta(p, \sigma) \equiv \delta(q, \sigma)$ for all $1 \leq i \leq n$.

The computation of the family $(\equiv_{j+1})_{j \geq 0}$ can then be done by successive approximations until reaching the stable point. 

**Lemma 1.** For $k \geq Q - 2$, we have $\equiv_{k+1} = \equiv_k$.

To prove this lemma, one has to use the property that each cycle's length cannot exceed $Q - 2$ (the number of nodes in one graph).
Algorithm 1. Tree automata minimization.

function MinimizationDFTA $A = (Q, \Sigma, Q_f, \Delta)$

$P_0 \leftarrow Q$

$P_i \leftarrow \{Q \setminus Q_f \}$

$i \leftarrow 1$

repeat

create $P_{i+1}$ by refining $P_i$ so that $p \equiv_{i+1} q$ iff for all $\rho \in \bigcup \Sigma \times Q^* \setminus \delta(p, \rho)$ and $\delta(q, \rho)$ are in the same partition in $P_i$

$i \leftarrow i + 1$

until ($P_{i+1} = P_i$)

$Q_{min} \leftarrow \{\{q\} | q \in Q\}$

$\Delta_{min} \leftarrow \{\{(s, q), \{s, q\}\} | (s, q) \in \Delta\}$

$Q_{min} \leftarrow \{\{q\} | q \in Q_f\}$

return $\Delta_{min} = (Q_{min}, \Sigma, Q_{min}, \Delta_{min})$

end function

Algorithm 1 describes in a general way the standard tree automata minimization. It iterates over a sequence of steps. First, the initial partition is set to $\{Q\}$ and the second one to $\{Q_f \setminus Q\}$. Next, at each iteration $i$, the current partition $P_i$ is split by computing $\equiv_i$. Then, we construct $Q_{min}$, the current partition $i$, and the second one to $Q_{min}$. Mind that we use a different $\Sigma$-node for each equivalence class of the state $q$.

4.2 Standard Implementation

By means of the associated graph proposed above, we see that the properties of equivalence can easily be extracted and checked. Thus, the representation promotes the minimization process.

We define some properties simplifying the verification of possible equivalences between the states.

Definition 4. Let $q$ be a state-node such that $(x, q) \in A$. Then the neighbours set of $q$ with respect to $x \in X_q$ is $N_q(x) = \{(p, \gamma(x, p)) | (x, p) \in A, p \neq q\}$.

Proposition 1. Let $p, q \in Q$. Then $p \equiv q \Leftrightarrow \forall x \in X_p \exists y \in X_q : lab(x) = lab(y) \wedge N_q(p) = N_p(q)$. 

Algorithm 1. Tree automata minimization.

```
function MinimizationDFTA \( A = (Q, \Sigma, Q_f, \Delta) \)
\( Q_0 \leftarrow Q \)
\( P_1 \leftarrow \{Q_0 - Q_f\} \)
i \leftarrow 1
repeat
create \( P_{i+1} \) by refining \( P_i \) so that \( p \equiv q \) iff for all \( \rho \in \bigcup \Sigma, \delta(\rho, p) \text{ and } \delta(\rho, q) \) are in the same partition in \( P_i \)
i \leftarrow i + 1
until \( P_i = P_{i+1} \)
\( Q_{\min} \leftarrow \{Q_0\} \)
\( \Delta_{\min} \leftarrow \{ (\sigma, q_1, ..., q_n) \mid (q_1, q_2, ..., q_n) \in \Delta \} \)
\( Q_{\min} \leftarrow \{q\} \mid q \in Q_f \)
return \( \min_{Q, \Delta} (Q_{\min}, \Delta_{\min}) \)
end function
```

Algorithm 1 describes in a general way the standard tree automata minimization. It iterates over a sequence of steps. First, the initial partition is set to \( \{Q_0\} \), and the second one to \( \{Q_0 - Q_f\} \). Next, at each iteration \( i \), the current partition \( P_i \) is split by computing \( \equiv \). At each step, \( k \) is decreased until it reaches 0.

4. Efficient Implementation of the Standard Minimization

In this section, we give an efficient data structure in favour of minimization and we introduce some useful properties. Next, we describe an algorithmic implementation of tree automata minimization after discussing the standard case.

Definition 1. The graph \( G_f = (X, \text{lab}, A, \gamma) \) associated to a DFTA \( A = (Q, \Sigma, Q_f, \Delta) \) is defined as follows:

- The \( \Sigma \)-nodes set \( X_\Sigma \) is any set, such that there exists a bijection \( X_\Sigma \rightarrow \Delta \).
- \( X = X_\Sigma \cup Q \) is the nodes set. \( Q \) is the \( \Sigma \)-nodes set (every state is a node in the graph).
- \( \text{lab} : X \rightarrow \Sigma \cup Q \) is the labels function that returns the label of each node from \( X \).
- \( A \subseteq (X_\Sigma \times \Sigma) \cup (Q \times X_f) \) is the arcs set.
- \( \gamma : A \rightarrow \mathbb{N} \) is a function that affects a weight for each arc.

Let \( \sigma \subseteq (\Sigma \times \Sigma) \cup Q \times Q \) and \( q_1, q_2 \subseteq Q \). We associate a set of arcs \( \{\{q_1, q_2\} \mid 0 \leq i \leq n\} \), such that:

- \( \text{lab}(q_i) = \sigma \).
- \( q_1, \text{lab}(q_i) = q_2, \text{lab}(q_i) = q \).
- \( q_1, x, \text{lab}(q) = 0 \).
- \( q_1, x, \text{lab}(q) = 1 \), \( 1 \leq i \leq n \).

Mind that we use a different \( \Sigma \)-node for each equivalence class (if all states are final and share the same up level).

4.1. Efficient Initialization

Obviously, we can meet only one equivalence class (if all states are final and share the same up level). Otherwise, this number can be equal at most to the number of states (if the processed automaton is already minimal). However, the number of equivalence classes can previously be bounded in order to accelerate the refinement process. Here we introduce some properties necessary but not sufficient to decide if two states are equivalent or not.

But first, let us recall an interesting property defined by Carrasco et al. [17].

\[ \text{sig}(q) = \begin{cases} \left( \sigma, q_1, ..., q_n \right) \in \Delta, & q_1, 1 \leq k < n \bigcup \{\left(\theta, 1\right)\} \text{ if } q \in Q_f \\ \emptyset \text{ otherwise} \end{cases} \]

Here the symbol \# is used to distinguish final states from non-final ones.

In fact, the signature \( \text{sig}(q) \) computes the similarity of left and right sides between states’ occurrences in the transitions set. We propose a "vertical" verification based on what we call states level.

Definition 2. The paths set of a state \( q \) denoted \( q \) is the set of all finite sequences \( q_1, ..., q_n, q \) such that \( q_1 \in Q, q_2, ..., q_n \in Q, n \leq |Q| \) and for each \( q_1, ..., q_i \), there exists a \( \Sigma \)-node \( x \) such that \( (q_1, x) \in A \). In other words, only arcs of non-null weight are considered in the path from a final state to the wanted one.

Definition 3. Let \( q \in Q \) be a state. Then the level of the state \( q \) is defined as \( \text{lev}(q) = \min_{\text{sig}(q)} \|q\| \). \( \|q\| \) is the length of the sequence \( q \).

Lemma 3. The levels of a DFTA states can be computed in linear time.

Obviously, the states level can be computed "on the fly" by executing a breadth-first search starting from final states. A special node may be added to give an entry to all final states nodes. Consequently, the following property remains true.

Lemma 4. Let \( p, q \in Q \). Then, \( p \equiv q \Leftrightarrow (\text{sig}(p) = \text{sig}(q) \land \text{lev}(p) = \text{lev}(q)) \).

4.2 Standard Implementation

By means of the associated graph proposed above, we see that the properties of equivalence can easily be extracted and checked. Thus, the representation promotes the minimization process.

We define some properties simplifying the verification of possible equivalences between the states.

Definition 4. Let \( q \) be a state-node such that \( (x, q) \in A \). Then the neighbours set of \( q \) with respect to \( x \) in \( X_q \) is \( N_q(x) = \{ (p, \text{lab}(x, p)) \mid (x, p) \in A, p \neq q \} \).

Proposition 1. Let \( p, q \in Q \). Then \( p \equiv q \Leftrightarrow (\forall x \in X_q \exists y \in X_q : \text{lab}(x) = \text{lab}(y) \land N_q(x) = N_q(y)) \).
Efficient Implementation for Deterministic Finite Tree Automata Minimization

4.3 An nlognn Algorithm

Now, we adapt the smallest half processing strategy involved in DFA Hopcroft minimization [7] to trees. Indeed, this strategy resolves effectively the problem of partition refinement. It consists of using a splitter (an argument in our case) to split a partition, while ensuring that pairs of states present in the new partition are necessarily inequivalent. Then, the smallest partition is chosen to continue the process.

Algorithm 2. Half processing standard minimization.

\( P \leftarrow \text{initialize}(Q) \)
\( S \leftarrow \text{smallSet}(P) \)
\( T \leftarrow \emptyset \)
for all \( s \in S \) do
    Treat \( s \) \( \rightarrow \emptyset \)
end for
while \( T \neq \emptyset \) do
    let \( T = (S, \sigma, \rho) \) Treat
    for all \( p \in P \) and \( s \in \Sigma \) do
        let \( b \in P \)
        for \( j = 1 \) to Arity(\( p \)) do
            \( p_1 \leftarrow \{ q \mid 3x \in F_s \colon N_s(q) = \text{succ}(x) - (q, \lambda) \text{ and } x \in S \} \)
            \( p_2 \leftarrow \rho - p_1 \)
        end for
        if \( \exists x \in X_s : (p, y) \in T \)
            replace \( (p, y) \) by \( (p_1, y), (p_2, y) \) in \( T \)
        else
            \( T \leftarrow T \cup \text{smallSet}(p_1, p_2) \)
        end if
    end for
    reset(\( P \))
end while

Proof. This case is trivial. Let \( p, q \in Q \) such that \( \exists x \in X_s : \text{lab}(x) = \text{lab}(y) \) \( \land \) \( N_s(p) \neq N_s(q) \) then using Definition 4 there exists \( (p, y, (x, p')) \in N_s(p) \) which does not figure in \( N_s(q) \). This leads to the fact that the transition \( (\text{lab}(x), q_1, \ldots, q_n) \in \Delta \) such that \( \rho \left( y, (x, p') \right) \neq \lambda, \ldots, q_n \) does not satisfy the definition of \( \Delta \).

We put \( p \neq q \iff \exists x \in X_s : \text{lab}(x) = \text{lab}(y) \) \( \land \) \( N_s(p) = N_s(q) \). Thus, this equivalence can be used in an alternative implementation by refining the initial partition of the minimization process until reaching the fixed point.

Definition 5. Let \( x \in X_s \), then the predecessor \( \text{pred}(x) \) of \( x \) is \( \text{pred}(x) \) such that \( (q, x) \in A \). The successors set \( \text{succ}(x) \) of \( x \) is \( \text{succ}(x) = \{ (q, \text{lab}(x)) \mid (x, q) \in A \} \).

Recall that the predecessor of a state-node represents the output of one transition that is unique (determinism).

To each symbol \( s \in \Sigma \) a set of \( \Sigma \)-nodes denoted \( F_s = \{ x \mid \text{lab}(x) = s \} \) is associated.

We give a general algorithm (Algorithm 2). The function initialize partitions the states set according to Lemma 4. Concerning the function smallest, it returns the smallest partition in the set given as a parameter. The algorithm deals with a set of couples from \( P : 2^\Sigma \times X_s \) which is used by the function reset so that the equivalence classes of a given iteration can be computed.

Theorem 1. Algorithm 2 effectively minimizes an automaton \( A = (Q, \Sigma, \delta, \lambda, \lambda) \) in \( \mathcal{O}(|\mathcal{A}| \log(|Q|)) \). This result can be checked using the same steps as in [7] and then reaches \( \mathcal{O}(|Q| \log(|Q|)) \) time complexity. However, instead of using a symbol from the alphabet to split states sets -- like in string case, one can use the property \( \exists x \in F_s : N_s(q) = \text{succ}(x) - (q, \lambda) \text{ and } x \in S \). Then, due to the maximum rank of the alphabet, and the size of \( X_s = |\Delta| \), the complexity will be \( \mathcal{O}(|\mathcal{A}| + |Q|) \log(|Q|) = \mathcal{O}(|\mathcal{A}| \log(|Q|)) \).

Mind that if \( |\Sigma| \) is not considered as constant, the whole complexity will be \( \mathcal{O}(|\mathcal{A}| \log(|Q|)) \).

5. New Incremental Implementation

In this section, we present an efficient implementation of the incremental DFTA minimization. It intends to reduce the asymptotic complexity of that proposed by Cleophas et al. [10] and that mentioned in [21]. It improves the incremental algorithm by means of the proposed associated graph introduced above. In what follows, we consider the DFTA \( A = (Q, \Sigma, \delta, \lambda) \) and its associated graph \( G_A = (X, \text{lab}, \lambda, \gamma) \).

In fact, since the algorithm of Cleophas does not propose any storage technique, the worst-case complexity is \( \mathcal{O}(\mathcal{A}^{0.5} \log^2(\mathcal{Q})) \).

However, despite its high complexity, this algorithm can be halted at any time resulting in a partially minimized automaton.

Reducing extra computations has been massively studied for FSA [24] and for DFTA [25]. One of the proposed improvements is the use of a particular set \( D \) representing distinguishability. However, the set \( D \) may be greedy in memory, it is clear that the relation \( \equiv \) is not an equivalence or an order relation (\( \equiv \) is not reflexive and it is not transitive).

First, we define two particular sets: \( J \) for equivalent states and \( D \) for distinguishable ones.

\[ J(p) = \{ q \in Q \mid p \equiv q \} \]
\[ D(p) = \{ q \in Q \mid p \not\equiv q \} \]

Next, we can intuitively deduce the following properties:

Let \( p, q \in Q \):

\( J(p) \cap J(q) \neq \emptyset \Rightarrow p \equiv q \)
\( D(p) \cap D(q) \neq \emptyset \Rightarrow p \not\equiv q \)

Indeed, before verifying if two states are equivalent, one can check these properties in order to decide if the recursive call has to be executed. By implementing \( J \) and \( D \) as bit-vectors, we can get at most \( \log(|Q|) \) verifications at each step.

We note that Lemma 4 can be used to initialize \( D \) with the states having different signatures.

By analogy to FSA [9], incremental technique may be very useful when dealing with both cyclic and acyclic cases. Thus, detecting cycles is useful in order to identify the nature of the DFTA to be minimized.

For this reason, we propose the following lemma which can be considered as a direct consequence of the pumping lemma on trees (see [8]).

Lemma 5. Let \( q \in Q \). Let \( t \in L(q) \), then if \( t = \emptyset \), then \( q \in L(q) \) and \( q \not\equiv \emptyset \) in a cycle and \( L(q) \) is infinite.

The proof of this lemma is simple. Knowing that the automaton is deterministic, if a tree belonging to a state’s down language is a subtree of another tree accepted by the same state, this tree must be met more than once in one traversal (path).

Consequently, if the DFTA is cyclic, then there exist some states in which computation of \( A \) runs infinitely. In terms of graphs, this is expressed obviously through graph cycles. As a direct result of this lemma:

Corollary 1. The DFTA \( A \) is cyclic if and only if there exists \( q \in Q \) such that we can find a sequence \( q, q_1, \ldots, q_n = q \) such that \( q \not\equiv q_1, \ldots, q_n \not\equiv q \) such that \( q \not\equiv q_1, \ldots, q_n \not\equiv q \). However, cycles number in a graph can grow exponentially w.r.t arcs number [25]. Fortunately, some search algorithms can naturally detect sets of nodes participating in a cycle. One excellent solution is to compute the strongly connected graph. There exist several linear algorithms in literature that find strongly-connected components of a graph in linear time like [26]. In our case, this step takes \( \mathcal{O}(|\mathcal{Q}| + |\mathcal{A}|) \) (arc number depends on transitions size).

Now, taking into account that the computation of strongly connected components gives a partition of the graph nodes, we put \( \Pi_s(G_A) \) the cycle-states set partitioning of the DFTA which contains portions of \( Q \). The strongly connected component containing the state \( q \). Therefore, we have:
Efficient Implementation for Deterministic Finite Tree Automata Minimization

4.3 An nlogn Algorithm

Now, we adapt the smallest half processing strategy involved in DFA Hopcroft minimization [7] to trees. Indeed, this strategy resolves effectively the problem of partition refinement. It consists of using a splitter (an argument in our case) to split a partition, while ensuring that pairs of states present in the new partition are necessarily inequivalent. Then, the smallest partition is chosen to continue the process.

Algorithm 2. Half processing standard minimization.

\[
P \leftarrow \text{initialize}(Q) \\
S \leftarrow \text{small}(P) \\
\text{ Treat } \rightarrow \emptyset \\
\text{ for all } \sigma \in S \text{ do } \\
\text{ Treat } \leftarrow \text{Treat } \cup \{(S, \sigma)\} \\
\text{ end for } \\
\text{ while Treat } \neq \emptyset \text{ do } \\
\text{ let } T = (S, \sigma) \text{ in Treat } \\
\text{ Treat } \leftarrow \text{Treat } \setminus \{T\} \\
\text{ for all } p \in P \text{ and } \sigma \in \Sigma \text{ do } \\
\text{ let } k \in P \\
\text{ for } i = 1 \text{ to \text{Arity}(\sigma) do } \\
p_1 \leftarrow \{q \mid 3x \in F_r \colon N_r(q) = \text{succ}(x) - (q, \lambda) \wedge \text{pred}(x) \in S\} \\
p_2 \leftarrow P - p_1 \\
\text{ end for } \\
\text{ if } \exists j \in X_r \colon (p, j) \in T \\
\text{ replace } (p, j) \text{ by } (p_1, j), (p_2, j) \text{ in } T \\
\text{ else } \\
T \leftarrow T \cup \text{smallest}(p_1, p_2) \\
\text{ end if } \\
\text{ reset}(P) \\
\text{ end while } \\
\]

Definition 5. Let \( x \in X_r \), then the predecessor pred(x) of \( x \) is pred(x) := \{q \mid (q, x) \in A\}. The successors set succ(x) of \( x \) is succ(x) := \{(q, y(x, p)) \mid (x, q) \in A\}.

Recall that the predecessor of a state-node represents the output of one transition that is unique (determinism).

To each symbol \( \sigma \in \Sigma \), a set of \( \Sigma \)-nodes denoted \( F_\sigma = \{x \mid \text{lab}(x) = \sigma\} \) is associated.

We give a general algorithm (Algorithm 2). The function initialize partitions the states set according to Lemma 4. Concerning the function smallest, it returns the smallest partition in the set given as a parameter. The algorithm deals with a set of couples from \( P : 2^V \times X_r \) which is used by the function reset so that the equivalence classes of a given iteration can be computed.

Theorem 1. Algorithm 2 effectively minimizes an automaton \( A = (Q, \Sigma, Q_0, \Delta) \) in \( O(|\Lambda| \log(|Q|)) \).

This result can be checked using the same steps as in [7] and then reaches \( O(|\Lambda| \log(|Q|)) \).

5. New Incremental Implementation

In this section, we present an efficient implementation of the incremental DFTA minimization. It intends to reduce the asymptotic complexity of that proposed by Cleophasa et al. [10] and that mentioned in [21]. It improves the incremental algorithm by means of the proposed associated graph introduced above. In what follows, we consider the DFTA \( A = (Q, \Sigma, Q_0, \Delta) \) and its associated graph \( G_A = (X, \lambda, A, \gamma) \).

In fact, since the algorithm of Cleophas does not propose any storage technique, the worst-case complexity is \( O(|\Lambda|^{(\frac{1}{2} - \frac{1}{2})}) \).

However, despite its high complexity, this algorithm can be halted at any time resulting in a partially minimized automaton.

Reducing extra computations has been massively studied for FSA [24] and for DFTA [23]. One of the proposed improvements is the use of a particular set \( D \) representing distinguishability. However, the set \( D \) may be greedy in memory, it is clear that the relation \( \equiv \) is not an equivalence or an order relation (\( \equiv \) is not reflexive and it is not transitive).

First, we define two particular sets: \( J \) for equivalent states and \( D \) for distinguishable ones.

\[
J(p) = \{q \in Q \mid p \equiv q \wedge \|p\} \\
D(p) = \{q \in Q \mid p \not\equiv q\} \\
\]

Next, we can intuitively deduct the following properties:

Let \( p, q \in Q \):

\[
(J(p) \cap J(q) \neq \emptyset) \Rightarrow p \equiv q \\
(D(p) \cap D(q) \neq \emptyset) \Rightarrow p \not\equiv q \\
\]

Indeed, before verifying if two states are equivalent, one can check these properties in order to decide if the recursive call has to be executed. By implementing \( J \) and \( D \) as bit-vectors, we can get at most \( \log(|Q|) \) verifications at each step.

We note that Lemma 4 can be used to initialize \( D \) with the states having different signatures. By analogy to FSA [9], incremental technique may be very useful when dealing with both cyclic and acyclic cases. Thus, detecting cycles is useful in order to identify the nature of the DFTA to be minimized.

For this reason, we propose the following lemma which can be considered as a direct consequence of the pumping lemma on trees (see [8]).

Lemma 5. Let \( q \in Q \). Let \( t \in L^1(q) \), then if \( 3\gamma \in Q, r \in \text{Sub}(t) : (r \Rightarrow \gamma) \in L^1(q) \) then \( q \) appears in a cycle an \( L^1(q) \) is infinite.

The proof of this lemma is simple. Knowing that the automaton is deterministic, if a tree belonging to a state's down language is a subtree of another tree accepted by the same state, this tree must be met more than once in one traversal (path).

Consequently, if the DFTA is cyclic, then there exist some states in which computation of \( d \) runs infinitely. In terms of graphs, this is expressed obviously through graph cycles. As a direct result of this lemma:

Corollary 1. The DFTA \( A \) is cyclic if and only if there exists \( q \in Q \) such that we can find a sequence \( q, q_1, \ldots, q_n \in Q \), \( q \in q_1, \ldots, q_n \in Q \).

However, cycles number in a graph can grow exponentially w.r.t. arcs number [25]. Fortunately, some search algorithms can naturally detect sets of nodes participating in a cycle. One excellent solution is to compute the strongly connected graph. There exist several linear algorithms in literature that find strongly-connected components of a graph in linear time like [26]. In our case, this step takes \( O(|\Lambda|^{(\frac{1}{2} - \frac{1}{2})}) \) (arc number depends on transitions size).

Now, taking into account that the computation of strongly connected components gives a partition of the graph nodes, we put \( \Pi_f(G_A) \) the cycle-states set partitioning of the DFTA which contains portions of \( Q \). \( \pi(q) \) is the strongly connected component containing the state \( q \). Therefore, we have:
Lemma 6. Let \( p = (\sigma, q_1, ..., q_n) \) be an argument. Let \( p, q \in Q \) such that \( \delta(p_{\sigma_i}) = p' \) and \( \delta(q_{\sigma_i}) = q' \). Then if \( p' \in \pi(p) \land q' \not\in \pi(q) \) then \( p \not\equiv q \).

According to \( \equiv \), \( p' \) and \( q' \) should be equivalent. However, there exists a cycle from \( p \) to \( p' \), but not from \( q \) to \( q' \). By the same argument, \( p \) can be reached from \( p' \), but it is not the case for \( q \) and \( q' \). Therefore, we can say that \( p \) and \( q \) cannot be equivalent.

Corollary 2. The DFTA is acyclic if and only if \( \forall \pi \in \Pi, |\pi| = 1 \).

It is clear that no strongly connected component exists. Every partition contains only one state.

We extend the predecessor notion to state-nodes.

Definition 6. Let \( q \in Q \) be a state-node, then the predecessors set \( \text{pred}(q) \) of \( q \) is:
\[
\text{pred}(q) = \{ s \in \mathbb{X}^2 \mid (p, x) \in A \}
\]
However, despite the use of \( \mathcal{I} \) and \( \mathcal{D} \), the global complexity of the computation remains high (two states may be verified more than once).

To solve this problem, we define a special tree \( T \) storing for every inspected pair of states, the path of computation and the recursion depth. \( \text{addNode}(P, Q) \) is a function that adds the states pair \( Q \) to the pair \( P \) as a subtree in \( T \). We use also a function \( \text{subTree}(\pi) \) to regroup all pairs figuring in the subtree of the node in \( T \).

\( T \) is used afterwards to decide the equivalence of states pairs invoked in the recursive call \( \equiv \).

We are now ready to give the improved equivalence function presented by Algorithm 3. \( \text{update}(p, q, true) \) is a function that updates the sets \( \mathcal{I} \) and \( \mathcal{D} \) for a pair \( (p, q) \) of states according to the given boolean \( B \). \( B \) is set to true when \( p \) and \( q \) are equivalent. This one represents the knowledge about equivalence relation between \( p \) and \( q \) deduced previously in the process.

### Algorithm 3. New equivalence function.

```plaintext
function \equiv(p, q, k)
    if \( k = 0 \) then
        eq \leftarrow (p \in Q) \land (q \in Q)
    else if \( (\mathcal{I}(p) \cap \mathcal{I}(q)) \neq \emptyset \) or \( (p, q) \in S \) then
        eq \leftarrow true
    else if \( (\mathcal{D}(p) \cap \mathcal{D}(q)) \neq \emptyset \) then
        eq \leftarrow false
    else
        S \leftarrow S \cup \{(p, q)\}
        eq \leftarrow (p \in Q) \land (q \in Q)
        for x \in \text{pred}(p) do
            if \( \exists y \in \text{pred}(q), \text{lab}(x) = \text{lab}(y) \land N_p(p) = N_q(q) \land |\text{pred}(p)| = |\text{pred}(q)| \) then
                eq \leftarrow \neg \equiv(eq, \text{pred}(x), \text{pred}(y), k - 1)
            end if
        end for
        if \( q \) then
            update(p, q, false)
            break; // The loop is stopped here, \( \text{pred}(s), \text{pred}(u) \) must not be added to \( \{p, q\} \) in \( T \).
        end if
        addNode((p, q), \{\text{pred}(s), \text{pred}(u)\})
    end for
    S \leftarrow S \setminus \{(p, q)\}
end function
```

When the function \( \equiv \) is called, \( T \) is created, containing all tested pairs during recursive calls. To avoid the reuse of these states, we introduce a new algorithm (Algorithm 4) that treats \( T \). Here, we meet three cases:

1. \( \equiv \) returns true, then all pairs located in \( T \) will be equivalent,
2. \( \equiv \) returns false (\( \equiv \) meets a break) and the height of \( T \) is less than \( |Q| - 2 \), then all subtrees concerned by the break receive false. The remaining pairs receive true,
3. \( \equiv \) returns false and the height of \( T \) is \( |Q| - 2 \), then all subtrees participating in cycles (ensured before this step by CCSC computation) and those concerned by the break are stored in a special matrix \( \text{Stack} \). The remaining pairs receive true.

For implementation reasons, we can add a special markup of \( T \): the recursion depth (parameter \( k \)) is associated to each stored node.

We can restore every verified path from \( \text{Stack} \) through the algorithm \( \text{CallStack} \) (Algorithm 5).

### Algorithm 4. Trace treatment.

```plaintext
function \text{CallStack}(p, q)
    for all \( (q_1, q_2, k) \in \text{Stack}(p, q) \) do
        eq \leftarrow eq \land \equiv(q_1, q_2, k)
    end for
    return eq
end function
```

Now, we propose a specific preorder to optimize \( \equiv \) calls.

### Algorithm 5. Verify stack.

```plaintext
function \text{CallStack}(p, q)
    for all \( (q_1, q_2, k) \) do
        eq \leftarrow eq \land \equiv(q_1, q_2, k)
    end for
    return eq
end function
```
Lemma 6. Let \( p = (\sigma, q_1, \ldots, q_n) \) be an argument. Let \( p, q \in Q \) such that \( \delta(p) = p' \) and \( \delta(q) = q' \). Then if \( p' \not\in \pi(p) \lor q' \not\in \pi(q) \) then \( p \neq q \).

According to (1), \( p' \) and \( q' \) should be equivalent. However, there exists a cycle from \( p \) to \( p' \), but not from \( q \) to \( q' \). By the same argument, \( p \) can be reached from \( p' \), but it is not the case for \( q \) and \( q' \). Therefore, we can say that \( p \) and \( q \) cannot be equivalent.

Corollary 2. The DFTA is acyclic if and only if \( \forall p \in P, |p| = 1 \).

It is clear that no strongly connected component exists. Every partition contains only one state.

We extend the predecessor notion to state-nodes.

Definition 6. Let \( q \in Q \) be a state-node, then the predecessors set \( \text{pred}(q) \) of \( q \) is:
\[
\text{pred}(q) = \{ x \in X_L \mid (p, x) \in A \}
\]

However, despite the use of \( \mathcal{J} \) and \( \mathcal{D} \), the global complexity of the computation remains high (two states may be verified more than once).

To solve this problem, we define a special tree \( \text{Trace} \) storing for every inspected pair of states, the path of computation and the recursion depth. \( \text{addNode}(P, Q) \) is a function that adds the states pair \( P \) to the pair \( Q \) as a subtree in \( \text{Trace} \). We use also a function \( \text{subTree}(\text{node}) \) to regroup all pairs figuring in the subtree of the node in \( \text{Trace} \).

\( \text{Trace} \) is used afterwards to decide the equivalence of states pairs invoked in the recursive call \( \text{equiv} \).

We are now ready to give the improved equivalence function presented by Algorithm 3.

\begin{algorithm}
\begin{algorithmic}
\Function{equiv}{$p, q$}
\If{$k < 0$}
\State $eq \leftarrow (p \in Q \land q \in Q)$
\ElsIf{\(\mathcal{J}(p) \cap \mathcal{J}(q) \neq \emptyset\) or \(p, q \in S\)}
\State $eq \leftarrow false$
\Else
\State $S \leftarrow S \cup \{p, q\}$
\State $eq \leftarrow (p \in Q \land q \in Q)$
\For{$x \in \text{pred}(p)$}
\If{$\exists y \in \text{pred}(q), \text{lab}(x) = \text{lab}(y) \land N_x(p) = N_y(q)$}
\If{$\text{pred}(x) \land \text{pred}(y) = \text{pred}(q)$}
\State $eq \leftarrow eq \land \text{equiv}(\text{pred}(x), \text{pred}(y), k - 1)$
\EndIf
\EndIf
\EndIf
\EndFor
\EndIf
\State $update(p, q, false)$
\State $break$  // The loop is stopped here, \( \text{pred}(s), \text{pred}(y) \) must not be added to \( \{p, q\} \) in \( \text{Trace} \).
\EndIf
\State $\text{addNode}(\{p, q\}, \text{pred}(s), \text{pred}(y))$
\EndFor
\State $S \leftarrow S \setminus \{p, q\}$
\EndIf
\State $return(eq)$
\EndFunction
\end{algorithmic}
\end{algorithm}

Now, we propose a specific preorder to optimize \( \text{equiv} \) calls.

Let \( p, q \in Q \). Then we put \( p \preceq q \iff L(p) \leq L(q) \).

It is clear that this preorder is total.

Corollary 3. There exists \( p \in Q \) such that \( \forall q \in Q : q \preceq p \land L(p) \leq L(q) \).

We can use this to decide if the state's level is bounded by \( |Q| \). This value comes from the longest path without cycles in a graph. It has an upper bound between the number of its nodes.

Following this preorder, we give the general rules of the incremental minimization process:

1. Start with testing final states equivalences (\( \forall p, q \in Q : L(p) = L(q) \)).
2. In each iteration, treat states already inspected during the previous steps. In other words, when an iteration \( \mathcal{I} \) is processed, treat states in the set \( \{p, L(p) = i\} \).

Algorithm 6 represents the main function. The function \( \text{CSCC}(G, \mathcal{A}) \) computes the strongly connected components of the graph associated
to the DFTA in question. Regarding the function \textit{InOut}(p, q), it returns a boolean indicating if \(p\) and \(q\) are equivalent or not, according to lemma 4 and lemma 6.

The defined main function uses two sets: \(V\) for verified states and \(R\) for states concerned by the next step. First, \(R\) is initialized by final states couples \(Qf\) (\(\forall q \in Qf \rightarrow \varnothing\)). Next, in each iteration, couples from \(R\) are verified and stored in \(V\). \(R\) is then updated to the next level. Finally, the algorithm ends when all possibilities are verified (\(V\) is stable). By verifying states in the main function and in the two guards \(D\) and \(J\), the following result is very important when dealing with the acyclic case.

**Corollary 4.** An ADFTA can be minimized in \(O(|A| \log(|Q|))\).

**Algorithm 6.** New main function.

```plaintext
function Main
    CSCC(A)
    \(S \leftarrow \varnothing\)
    for all \(q \in Q\) do
        \(\mathcal{N}(q) \leftarrow q\)
        \(\mathcal{D}(q) \leftarrow \varnothing\)
    end for
    \(R \leftarrow Qf\)  # The initial level is 0
    \(V \leftarrow \varnothing\)
    \(V' \leftarrow \varnothing\)
    repeat
        \(T \leftarrow \{ (p, q) | p \in Q \}\)
        for all \((p, q) \in R^2 - (V' \cup T)\) do
            \(\text{Traces}(\emptyset)\)
            if \(\text{InOut}(p, q)\) then
                update(p, q, false)
            else
                update(p, q, equiv(p, q, \(\mid Q \mid - 2\))
            end if
        end for
        \(H \leftarrow R\)
        \(V' \leftarrow V\)
        \(V' \leftarrow V' \cup R^2\)
        \(R \leftarrow \{ q \mid \exists h \in H, n \in N, x \in X_c : (x, q') \in \mathcal{E}, (x, q, q') \in A \} \)  # We have \(|L(q) + L(q')| = 1\)
        while \(V' > V\)
    end function
```

**Theorem 2.** A DFTA can be minimized using Algorithm 6 in \(O(|A| + |Q| \log(|Q|))\).

The main function executes exactly \(|Q|(|Q| - 1)/2\) calls. In each one, a \(|Q| - 2\) depth (ensured by \(k\)) new calls are made. Indeed, the predecessors and the neighbours’ sets (\(\mathcal{E}\) computation) can be computed before the incremental process. Mind that this can be done in \(O(|X|\log(|X|))\) for every \(x\)-node, \(\mathcal{E}\) states can be connected and the size of the whole graph is \(|A|\). Whereof, testing of these sets (Algorithm 3) can be done in a constant time. Furthermore, all duplicated computations can be avoided using \(\text{Trace}(\emptyset)\), \(\text{Stack}\) and the two guards \(D\) and \(J\).

6. Conclusion

In this work, we present an efficient implementation of DFTA minimization based on a simple graphic view of the automaton to be minimized. We show a general algorithm of the standard technique and we outline an adapted method based on the smallest half-strategy processing. The time complexity is \(O(|A| \log(|Q|))\).

The second part is dedicated to the incremental technique. We give an improved implementation based on graph properties and avoidance of some computations. The complexity of this algorithm is \(O(|Q| \log(|Q|))\). Moreover, we show that this technique minimizes an ADFTA in \(O(|A| \log(|Q|))\).

**References**

Theorem 2. A DFTA can be minimized using Algorithm 6 in $O(|\mathcal{A}| \log(|\mathcal{Q}|))$.

Indeed, it is not necessary to use $Trace$, $Stack$ and the depth guard $k$ in the acyclic case because no cycles are met. A native equivalence function $equiv(p, q)$ can be used instead of the improved one. Detecting DFTA nature can be done instantly by analysing the result of $CSCC(G' \cdot)$.

6. Conclusion

In this work, we present an efficient implementation of DFTA minimization based on a simple graphic view of the automaton to be minimized. We show a general algorithm of the standard technique and we outline an adapted method based on the smallest half-strategy processing. The time complexity is $O(|\mathcal{A}| \log(|\mathcal{Q}|))$.

The second part is dedicated to the incremental technique. We give an improved implementation based on graph properties and avoidance of some computations. The complexity of this algorithm is $O(|\mathcal{Q}| \log(|\mathcal{Q}|))$. Moreover, we show that this technique minimizes an ADFTA in $O(|\mathcal{A}| \log(|\mathcal{Q}|))$.
