**ABSTRACT** • *The use of juvenile wood has become quite frequent today. Juvenile wood differs from mature wood in its physical, mechanical and technological properties. Different properties of juvenile wood can have a further effect on processing and manufacturing of products. Therefore it is important to investigate all aspects of processing juvenile wood. The aim of this paper was to establish the influence of physical, mechanical and technological properties on granulometric composition and dimension analysis of juvenile pine wood chips in plane milling.*

**Key words:** *pine wood, juvenile wood, mature wood, plane milling, granulometric analysis*

**SAŽETAK** • *Uporaba juvenilnog drva danas je vrlo česta. To se drvo svojim mehaničkim, fizikalnim i tehnološkim svojstvima razlikuje od adultnog drva. Različita svojstva juvenilnog drva mogu imati značajan utjecaj na preradu drva i proizvodnju drvnih proizvoda. Zato je vrlo važno ispitati sve aspekte prerade juvenilnog drva. Cilj je ovog rada istražiti utjecaj fizikalnih, mehaničkih i tehnoloških svojstava juvenilnog drva na granulometrijski sastav i dimenzije čestica nastalih pri glodanju.*

**Ključne riječi:** *borovina, juvenilno drvo, adultno drvo, glodanje, granulometrijska analiza*

### 1 INTRODUCTION

#### 1. UVOD

It is taken for granted that juvenile wood will become much more significant in future by increasing the share of its processing. Changes can be expected in agricultural and forestry policy, mainly by afforestation

of unused agricultural land by fast plantation growing tree species. Therefore different properties of juvenile wood, compared to mature wood, must be taken into account, mainly with respect to its further processing.

In the process of milling, chips are generated whose shape, dimensions and quantity depends not only on physical and mechanical properties of milled

wood, but also on the shape, dimensions and sharpness of the cutting tool and technical and technological factors of the milling process.

In many studies, the properties of chips have been evaluated according to individual tree species and individual woodworking and cutting machines. No information can be found in the reference literature related exclusively to the properties of juvenile wood chips. Similarly, there is no comparison between juvenile wood and mature wood depending on specific technological conditions of cutting the wood.

In wood-processing industry, the transport of chips from the place of their origin is usually affected by an air-driven system. From the viewpoint of environmental criteria the air-driven system must be adapted to the changes of milled material as well as to the changes of technical and technological parameters. That is why it is important to specify the properties of disintegrated wood substance formed under particular conditions.

The paper aims at analysis of granularity of juvenile pine wood chips taken from the process of plane milling on conventional spindle moulding machine. The study also shows the differences between the chips generated from juvenile and mature pinewood. This analysis is followed by the experimental study of interactive relations between energy demands, wear of tool and quality of processing juvenile and mature pine wood in milling.

## 2 THEORETICAL ANALYSES

### 2. TEORIJSKE OSNOVE

#### 2.1 Juvenile wood

##### 2.1.1. Juvenilno drvo

Juvenile wood is defined as wood produced in the early growth of trees and found around the pith marked by physical, mechanical and technological properties, different from the properties of wood that is formed later.

#### 2.1.1 Physical properties of juvenile wood

##### 2.1.1. Fizikalna svojstva juvenilnog drva

The density of juvenile wood, compared to mature wood, is lower by approximately 5-15 %. Lower densities of juvenile wood were measured in the fast-growing pines grown in plantations whose density is lower by as much as 50 kg·m<sup>-3</sup> (Thörnqvist, 1993).

Swelling and shrinking of wood is proportional to the orientation of cellulose fibrils in the cell wall. Considering the above mentioned prevailing orientation of fibrils in the cell wall of normal wood, under an angle of 5°-15° wood swelling in longitudinal direction is very low, this value is practically negligible. The angle of the cellulose fibril arrangement in juvenile wood is considerably higher, which is manifested in substantial increase of longitudinal swelling of this wood. That is why the values of longitudinal shrinkage of juvenile wood often exceed these values by more than 1 %. The sawn-wood from juvenile wood is as a result of changed shrinkage strained by drying stresses, which is often manifested by shape instability connected with longitudinal and also transversal deformation of the given sawn-wood assortment (Thörnqvist, 1993).

Wood moisture content of freshly cut raw material with high portion of juvenile wood (young trees, tree tops and branches) is higher as a result of physiologically active sapwood, which includes the entire portion of wood in young stems. High portion of spring, porous wood is not negligible either. This fact could affect the acceptance of wood by weight method in pulp mills.

Pivolusková and Kotlínová (2004) present the comparison of physical properties of juvenile wood and older pine wood with data found in reference literature (Table 1).

#### 2.1.2 Mechanical properties of juvenile wood

##### 2.1.2. Mehanička svojstva juvenilnog drva

Mechanical properties of juvenile wood are mainly influenced by lower density of wood, caused by its chemical, sub-microscopic and microscopic structure.

Mechanical properties are influenced by the amount of chemical substances such as lignin, cellulose of hemicelluloses and extractive matters. The tilt angle of the cellulose fibrils with respect to the walls of fibrous cells is also very important.

Mechanical properties of juvenile wood are practically changed in all tree species in comparison with mature, normal wood. It could not be generally said which properties of juvenile wood are worse and which ones are better for a manufacturer. Zobel&Sprague (1998) state the greatest decrease in tensile strength. The tensile strength in American pine decreased to approximately 70 % from the value of normal wood. The tensile strength in Douglas fir of juvenile wood decreased to as much as 50 %. Similarly, although not to such an extent, the modulus of elasticity in juvenile wood decreased to approximately 90 % in pinewood and to approximately 70 % in Douglas fir.

The decreased mechanical properties of juvenile pinewood are also presented by Pivolusková and Kotlíňová, 2004 (Table 2).

## 2.2 Size and shape of chips

### 2.2. Veličina i oblik čestica

Size and shape of disintegrated particles of wood substance are the basic data characterizing loose wood substance. The above characteristics have an influence on physical properties of loose substance such as: apparent density, granulometric structure, angle of slip, angle of discharge. They also affect particles motion properties in the pipeline of the suction system and conditions of separation or filtration in the separation device.

The dimensions of particles are defined by dimensions of a rectangular parallelepiped circumscribed to a given particle, where length is the largest dimension of the particle, thickness is the smallest dimension of the particle, and width is the third dimension of the particle. The size of the particle is determined by the largest dimension of rectangular parallelepiped circumscribed around the particle i.e. length of a chip.

Dzurenda (2002) specifies that geometrical shapes of chips produced in cutting or wood processing are

of various shapes. This is indirectly proved by the particles of disintegrated wood substance shown in Figure 2. In spite of this fact, effort has been made to classify the grains of loose substances into one of the three basic groups:

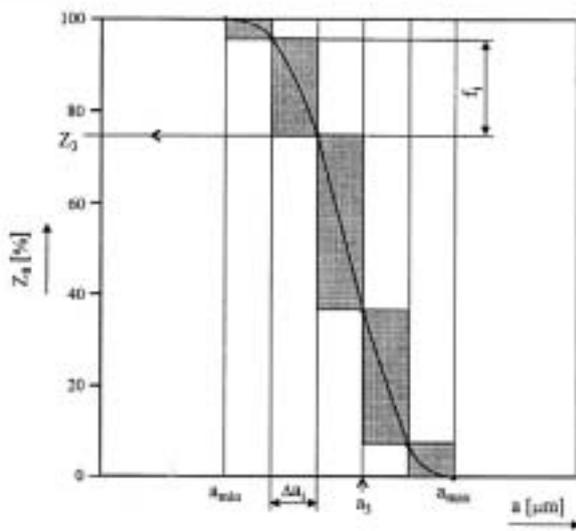

- Isometric grains – chips having approximately the same dimension in all three directions (fine fraction of chips and very fine fractions of saw dust) Dzurenda (2002).
- Flat grains (laminar) – the dimension of length and width in these grains are considerably larger than the third dimension, i.e. thickness of chips Dzurenda (2002).
- Threadlike grains (fibrous) – chips with pronounced elongation in one dimension (fibre, medium coarse and coarse fractions of saw dust, needle-like chips, and medium coarse fractions of wood dust Dzurenda (2002).

## 2.3 Granulometric analysis

### 2.3. Granulometrijska analiza

Granularity (granulometric composition) is an information characterising representation of individual particles (group of particles) of certain size in the whole set of loose substance. The most common method for the determination of granulometric composition is sieving i.e. screening of the sample of loose substance through a sieve set with specific mesh sizes usually arranged from the largest to the smallest. The results of sieve analysis are presented in the form of a table or graphically in the form of a distribution curve  $D_a$ , or integral curve of granularity (the curve of oversizes  $P_a$ , or the curve of screen residue  $Z_a$ ).

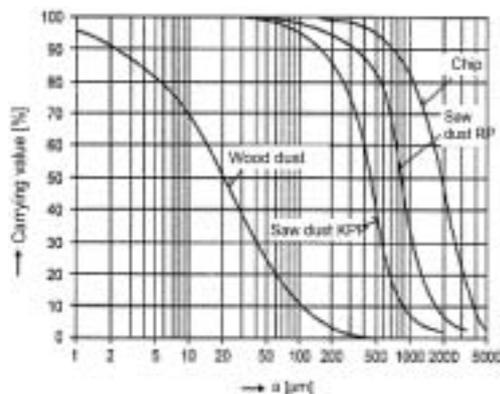

The curve of screen residue  $Z_a$  (Figure 1) expresses the dependence of relative weight of grains bigger than the particle size in the analysed sample  $Z_i$  (%) on the particle size  $a$  ( $\mu\text{m}$ ). The curve from screen residue is formed analogically as the curve of oversizes, i.e. by gradual plotting of dimensions of individual fractions  $f_i$  on the vertical axis. The difference in plotting screen residue curves compared with plotting oversizes curve is

**Figure 1** Curve of screen residue  $Z_a$   
**Slika 1.** Krivulja raspodjele veličina čestica  $Z_a$

that the projection of fraction of values is made from the fraction of the biggest particles (Dzurenda, 2002).

The curve of screen residue or oversizes is often displayed in logarithmic-normal grid (Figure 2). In this grid the values of particle sizes  $a_i$  are projected on logarithmic scale (horizontal axis), and the quotients of fractions  $f_i$  are projected on linear scale. Considerable part of the curve of oversizes or the curve of screen residues is in this scale displayed by straight line, which is the main advantage of this form of screen analysis presentation.

**Figure 2** Curves of screen residue in logarithmic-normal grid  
**Slika 2.** Krivulja raspodjele čestica (logaritamska skala)

### 3 MATERIAL AND METHODS 3. MATERIJAL I METODE

Experimental tests were carried out on samples of pine (*Pinus sylvestris*), coming from the region of Zubačková bučina, cadastral zone - Podzámčok (School Forest Enterprise), 450 m above sea level. Logs were used for cutting two quarter sawn boards, mostly consisting of juvenile wood. Subsequently they were both cut through the pith, cut to 1 m length, dried and air-conditioned at  $\varphi=65\%$  and  $t=20^\circ\text{C}$  to  $w=12\%$  of moisture content, mechanically dried, and processed to the thickness of 35 mm. These samples contained a large number of defects, which could not be neglected, as these defects are a natural part of juvenile wood and

hence, they cannot be ignored when determining its properties. Considered defects are mainly knots, which are the remnants of the first branches of a young tree.

All practical tests were carried out in VDL-TU (Development Workshops and Laboratories-Technical University Zvolen). The monitoring device consisted of a spindle moulding machine, feeding device, measuring apparatus and evaluation equipment designed for monitoring the cutting power. Individual samples (boards) were milled by standard milling under the following cutting conditions: feed rate  $v_f=2.5\text{ m}\cdot\text{min}^{-1}$  and  $v_f=15\text{ m}\cdot\text{min}^{-1}$ , cutting speed  $v_c=20\text{ m}\cdot\text{s}^{-1}$  and  $v_c=30\text{ m}\cdot\text{s}^{-1}$ , angular geometry of the milling machine:  $\beta_f=55^\circ$  (cutting edge angle),  $\gamma_f=15^\circ, 20^\circ, 25^\circ, 30^\circ$  (cutting face angle). During the measurement of the cutting power, in the framework of individual interactive influences, chips were removed at the same time (cca 200 g), removal of 1 mm by one cutting edge of the tool.

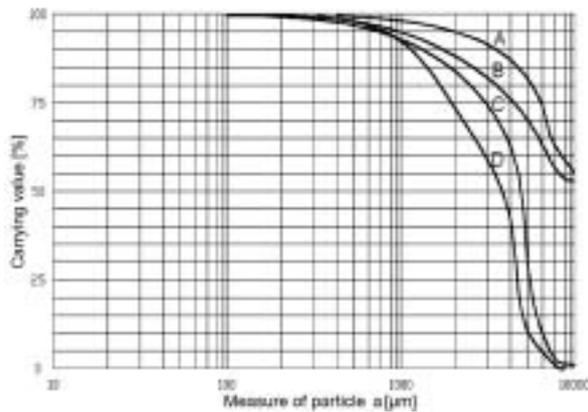

### 3.1 Process of granulometric analysis 3.1. Granulometrijska analiza

The screen analysis was carried out with the use of a Fritsch vibration screen machine by a testing sieve set in accordance with STN (Slovak Technical Norm) 15 3105 (STN ISO 3310-1). The standard does not define the exact time of sieving, nor the size or number of sieve meshes (Horák, 1996). On the basis of previous experiments, the sieves with the following mesh sizes were determined: 8; 6.3; 5; 4; 2 and 1 mm, as well as the time of sieving of 5 minutes. The measurements were carried out at average chips moisture of 12 %. The sieve set was mounted on the Fritsch vibration machine. The necessary amount of sample (100 g) was weighed on a laboratory scale and put to the upper sieve of the sieving machine. The set was then closed by a glass lid and continually sieved for 5 minutes. Upon sieving, individual sieving residues were weighed on a Bosch digital laboratory scale with the weighing accuracy to the nearest 0.001 g. After that the weight portions of individual sieves calculated in percentages were recorded in the form of a table and evaluated graphically. The procedure was repeated 3 times for each measured sample, to eliminate possible measurement error.

### 3.2 Process of dimensional analysis 3.2. Analiza veličine čestica

In order to carry out dimensional analysis, the evaluation was made of chips produced with angular parameters of the milling machine  $\gamma_f / \beta_f=15^\circ/55^\circ$  (cutting face angle/cutting edge angle) and both feeding speed ( $v_f=2.5\text{ m}\cdot\text{min}^{-1}$  and  $v_f=15\text{ m}\cdot\text{min}^{-1}$ ) and cutting speed ( $v_c=20\text{ m}\cdot\text{s}^{-1}$ ) were derived from the cutting parameters.

The analysis of chip dimensions was carried out by the Department of Wood Sciences. The CCD Mitsubishi scanned each combination of chips ten times. In the analysis of the biggest fraction exceeding 8 mm, 4.5 x magnification was used, and in the analysis of the smallest fraction under 1 mm - 125 x magnification was used. By means of Lucia G/Comet programme, dimensional picture analysis was made of each photo, namely

A – Juvenile wood,  $v_f = 2.5 \text{ m}\cdot\text{min}^{-1}$  B – Mature wood,  $v_f = 2.5 \text{ m}\cdot\text{min}^{-1}$   
 C – Juvenile wood  $v_f = 15 \text{ m}\cdot\text{min}^{-1}$  D – Mature wood,  $v_f = 15 \text{ m}\cdot\text{min}^{-1}$   
 A – juvenilno drvo,  $v_f = 2,5 \text{ m}\cdot\text{min}^{-1}$  B – adultno drvo,  $v_f = 2,5 \text{ m}\cdot\text{min}^{-1}$   
 C – juvenilno drvo  $v_f = 15 \text{ m}\cdot\text{min}^{-1}$  D – adultno drvo,  $v_f = 15 \text{ m}\cdot\text{min}^{-1}$

**Figure 3** Screen residue curves of pine chips at cutting speed  $v_c = 20 \text{ m}\cdot\text{s}^{-1}$

**Slika 3.** Krivulja raspodjele veličina čestica borove strugotine pri brzini rezanja  $v_c = 30 \text{ m}\cdot\text{s}^{-1}$

the length and width in mm, and the obtained values were statistically processed.

## 4 RESULTS AND DISCUSSIONS

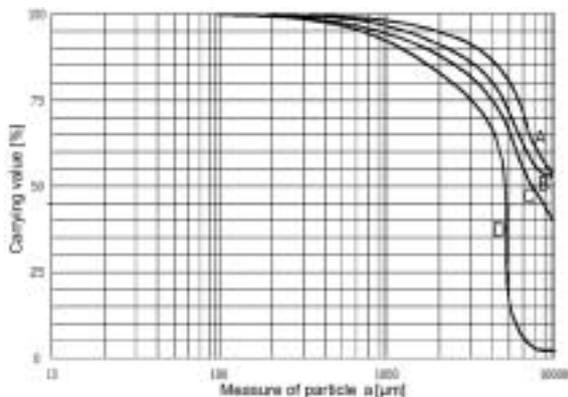

### 4. REZULTATI I DISKUSIJA

#### 4.1 Granulometric analysis

##### 4.1. Granulometrijska analiza

The curves of granulometric composition of pine chips produced in plane milling with the combination of specific parameters and angular geometry  $\gamma_f / \beta_f = 15^\circ / 55^\circ$  are shown in Figures 3-6 by means of screen residue curves.

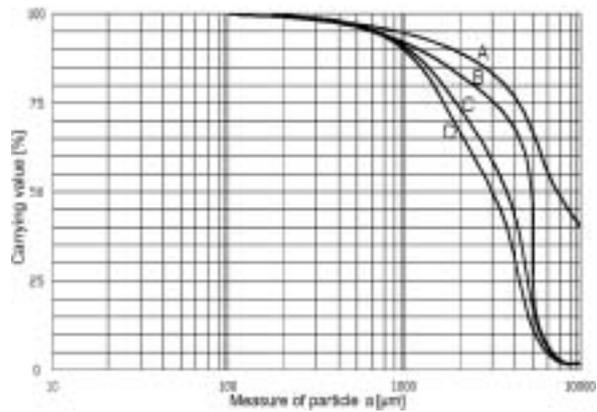

The results with combinations of angular geometry  $\gamma_f / \beta_f = 20^\circ / 55^\circ, 25^\circ / 55^\circ$  and  $30^\circ / 55^\circ$  are not presented, because granulometric composition of chips is

A – Juvenile wood,  $v_c = 20 \text{ m}\cdot\text{s}^{-1}$  B – Mature wood,  $v_c = 20 \text{ m}\cdot\text{s}^{-1}$   
 C – Juvenile wood,  $v_c = 30 \text{ m}\cdot\text{s}^{-1}$  D – Mature wood,  $v_c = 30 \text{ m}\cdot\text{s}^{-1}$   
 A – juvenilno drvo,  $v_c = 20 \text{ m}\cdot\text{s}^{-1}$  B – adultno drvo,  $v_c = 20 \text{ m}\cdot\text{s}^{-1}$   
 C – juvenilno drvo,  $v_c = 30 \text{ m}\cdot\text{s}^{-1}$  D – adultno drvo,  $v_c = 30 \text{ m}\cdot\text{s}^{-1}$

**Figure 5** Screen residue curves of pine chips at feeding speed  $v_f = 2.5 \text{ m}\cdot\text{min}^{-1}$

**Slika 5.** Krivulja raspodjele veličina čestica borove strugotine pri posmičnoj brzini  $v_f = 2,5 \text{ m}\cdot\text{min}^{-1}$

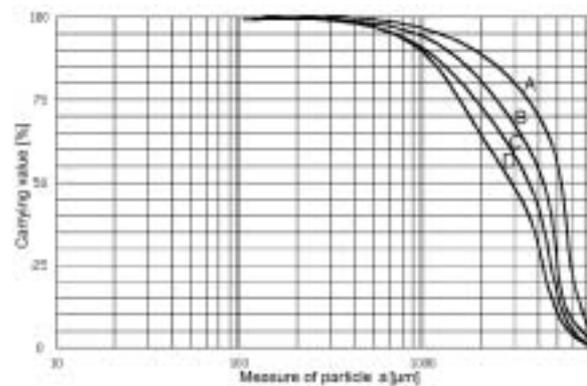

A – Juvenile wood,  $v_f = 2.5 \text{ m}\cdot\text{min}^{-1}$  B – Mature wood,  $v_f = 2.5 \text{ m}\cdot\text{min}^{-1}$   
 C – Juvenile wood,  $v_f = 15 \text{ m}\cdot\text{min}^{-1}$  D – Mature wood,  $v_f = 15 \text{ m}\cdot\text{min}^{-1}$

 C – juvenilno drvo,  $v_f = 15 \text{ m}\cdot\text{min}^{-1}$  D – adultno drvo,  $v_f = 15 \text{ m}\cdot\text{min}^{-1}$

**Figure 4** Screen residue curves of pine chips at cutting speed  $v_c = 30 \text{ m}\cdot\text{s}^{-1}$

**Slika 4.** Krivulja raspodjele veličina čestica borove strugotine pri brzini rezanja  $v_c = 20 \text{ m}\cdot\text{s}^{-1}$

similar to all types of angular geometry both in juvenile and mature wood.

Significant difference in granulometric composition of pine chips was found by the change of feeding speed from  $v_f = 2.5 \text{ m}\cdot\text{min}^{-1}$  to  $v_f = 15 \text{ m}\cdot\text{min}^{-1}$ , as well as by the change of cutting speed from ( $v_c = 20 \text{ m}\cdot\text{s}^{-1}$ ) to  $v_c = 30 \text{ m}\cdot\text{s}^{-1}$ , but only in combination with feeding speed  $v_f = 2.5 \text{ m}\cdot\text{min}^{-1}$ . In combination with the feeding speed  $v_f = 15 \text{ m}\cdot\text{min}^{-1}$  the influence of cutting speed was not significant. With regard to the percentage ratio of individual fractions, no significant difference was recorded between juvenile and mature wood. The only significant difference was recorded in the combination of cutting speed  $v_c = 30 \text{ m}\cdot\text{s}^{-1}$  and feeding speed  $v_f = 2.5 \text{ m}\cdot\text{min}^{-1}$ , where juvenile wood had the most numerous fraction over 8 mm and mature wood over 4 mm. Small differences (mainly various changes - increase or decrease with

A – Juvenile wood,  $v_c = 20 \text{ m}\cdot\text{s}^{-1}$  B – Mature wood,  $v_c = 20 \text{ m}\cdot\text{s}^{-1}$   
 C – Juvenile wood,  $v_c = 30 \text{ m}\cdot\text{s}^{-1}$  D – Mature wood,  $v_c = 30 \text{ m}\cdot\text{s}^{-1}$   
 A – juvenilno drvo,  $v_c = 20 \text{ m}\cdot\text{s}^{-1}$  B – adultno drvo,  $v_c = 20 \text{ m}\cdot\text{s}^{-1}$   
 C – juvenilno drvo,  $v_c = 30 \text{ m}\cdot\text{s}^{-1}$  D – adultno drvo,  $v_c = 30 \text{ m}\cdot\text{s}^{-1}$

**Figure 6** Screen residue curves of pine chips at feeding speed  $v_f = 15 \text{ m}\cdot\text{min}^{-1}$

**Slika 6.** Krivulja raspodjele veličina čestica borove strugotine pri posmičnoj brzini  $v_f = 15 \text{ m}\cdot\text{min}^{-1}$

different cutting parameters) in percentage ratio between juvenile and mature wood were probably caused by heterogeneity of juvenile wood, by numbers of knots, imperfect parallelism of wood fibres with regard to cutting line, inaccuracy of working, cutting conditions, and by intensity of blunting the cutting edge of the tool.

Based on all combinations of cutting parameters it can be concluded that the highest share of the smallest fraction of chips was created in using the highest cutting speed  $v_c=30 \text{ m}\cdot\text{s}^{-1}$  and the highest feeding speed  $v_f=15 \text{ m}\cdot\text{min}^{-1}$ . The reason lies in the fact that the contact between the cutting tool and working piece is shorter, by which smaller chips are produced. In this case, a lower proportion of the biggest fraction was also produced. The lower proportion of the smallest fraction of chips was produced by using the highest cutting speed  $v_c=30 \text{ m}\cdot\text{s}^{-1}$  and the lowest feeding speed  $v_f=2.5 \text{ m}\cdot\text{min}^{-1}$ , because the cutting tool rotates quickly, and the material moves slowly. As a result the cutting edge bites into the wood for the longest time, by which the longest chips are produced. So it means that in this combination of cutting and feeding speed, the highest share of the biggest fraction was produced. At lower cutting speed  $v_c=20 \text{ m}\cdot\text{s}^{-1}$  chips were produced in a similar process. However, in combination with a lower feeding speed, a lower proportion of the biggest fraction was produced.

The impact of the cutting speed was crucial in the percentage share of the largest fraction while the fee-

ding speed was crucial in the percentage share of the smallest fraction.

#### 4.2 Dimensional analysis

##### 4.2. Analiza veličine čestica

Within dimensional analysis of particle sizes, the basic dimensions were determined of the biggest particles of the coarse fraction of pine chips exceeding 8 mm (Table 3-4), Figures 7 and 8, and the dimensions of the smallest particles of fraction with dimensions under 1 mm (Table 5-6), Figures 9 and 10.

Based on the results of dimensional analysis of individual particles it can be concluded that most of disintegrated wood substance produced in the process of plane milling of pine wood can be classified into the group of flat grains – where the dimension of length and width is markedly larger than the third dimension, i.e. the thickness of chip. A small percentage of produced chips can be classified into the group of fibrous loose materials of stick-shaped form with pronounced elongation in one direction (smaller fractions created mainly in feeding speed  $v_f=2.5 \text{ m}\cdot\text{min}^{-1}$ ). Fine dust makes the last group (the smallest dust particles with dimensions  $29.2 \mu\text{m}$  in length and  $13.1 \mu\text{m}$  in width).

In dimensional analysis the difference of fractions between juvenile and mature wood is not pronounced. The maximum and minimum values of dimen-

sions (length, width) of juvenile and mature wood are similar. The difference between juvenile and mature wood is recorded in their average values of dimensions. With mature wood lower average values were measured of width in the biggest and smallest fraction. With regard to length, lower average values were recorded in

juvenile wood (with the feeding speed  $v_f=15\text{ m}\cdot\text{min}^{-1}$  and the smallest fraction – lower by 31 % compared to mature wood). It can be concluded that in milling juvenile wood, shorter and wider fractions are more frequent than in milling mature wood. This is caused by lower hardness and higher fragility of wood; regarding

**Figure 9** The smallest fraction (under 1 mm) of chips from juvenile pine wood with angular geometry of the milling machine  $\gamma_f/\beta_f=15^\circ/55^\circ$  and cutting parameters  $v_c=20\text{ m}\cdot\text{s}^{-1}$ ,  $v_f=2.5\text{ m}\cdot\text{min}^{-1}$

**Figure 10** The smallest fraction (under 1 mm) of chips from mature pine wood with angular geometry of the milling machine  $\gamma_f/\beta_f=15^\circ/55^\circ$  and cutting parameters  $v_c=20\text{ m}\cdot\text{s}^{-1}$ ,  $v_f=2.5\text{ m}\cdot\text{min}^{-1}$

**Slika 10.** Prikaz čestica borovine manjih od 1 mm nastalih pri glodanju adultnog drva ( $\gamma_f/\beta_f=15^\circ/55^\circ$ ,  $v_c=20\text{ m}\cdot\text{s}^{-1}$ ,  $v_f=2,5\text{ m}\cdot\text{min}^{-1}$ )

physical properties, density has the greatest influence on technological properties of wood. All these characteristics result from different anatomical and chemical structure of wood (thinner cell walls, shorter cells, lower proportion of summerwood and higher proportion of lignin, which increase the fragility of wood).

## 5 CONCLUSIONS

### 5. ZAKLJUČCI

The main aim of this paper was to research the influence of technological parameters (feeding speed, cutting speed, angular geometry of the milling machine) and the influence of wood (juvenile and mature wood) on the production of chips in plane milling; its granulometric composition and dimensions of the biggest particles (above 8 mm) and the smallest particles (under 1 mm). These data are important for designing the suction system and even more for adjusting the construction and type of the dust separator.

On the basis of the obtained results, it can be stated that the differences recorded between chips produced from juvenile and mature wood are not significant. Consequently there is no need to adapt the design of the sucking system and adjust the construction and type of the dust separator depending on the share and type of chip fractions, as the smallest and biggest chip fraction in juvenile and mature wood is similar. It means that it is not necessary to use another type of separating device in milling juvenile wood but the one commonly used in suction of chips produced in processing mature wood.
