THE EFFECT OF ETHYL ESTER OF APO CAROTENIC ACID (CAROPHYLL YELLOW) ON HEALTH, REPRODUCTION, MORPHOLOGICAL AND BIOCHEMICAL BLOOD PARAMETERS OF GEESE

DJELOVANJE ETHYL-ESTERA APO-KAROTINSKE KISELINE (CAROPHYLLA ŽUTOG) NA ZDRAVLJE, REPRODUKCIJU, MORFOLOŠKE I BIOKEMIJSKE PARAMETRE KRVI GUSAKA

Dorota Jamroz

SAŽETAK

Izvršeno je ukupno 5 pokusa za koje se sumarno prikazuju rezultati. U pokusima I do IV bilo je u svakoj grupi po 280 gusaka bijar. a talijanske pasmine a u pokusu V bilo je 1.820 gusaka. Svaka podgrupa sadržavala je 30 do 32 guske i 6 do 8 gusana jednu do dvije godine starosti. Svaka je grupa imala 3 do 4 ponavljanja. U tijeku proizvodnje period svjetla trajao je 8 sati dnevno.

Pokusne životinje razvrstane su u pokusne grupe polovicom prosinca a period nesenja počeo je u drugoj polovici siječnja. Pokus je trajao od prvog sneženog jajeta do završetka nesivosti polovicom lipnja. U tijeku pokusa pruženi su broj i težina jaja, fertilitet i sposobnost valjenja, uzimanje hrane, mortalitet i njihov uzrok.

U periodu nesivosti guske su dobivale hranu koja je sadržavala 10% dehidriran trave i male količine kuku ruza ili je bila bez kuku ruza (tablice 1, 5, 10, 15, 22). Sadržaj s, proteina bio je 15,8% u pokusu I a u ostalim pokusima varirao je od 13,3 do 13,8%. Vitamin A bio je konstantan 10.000 i/j/kg hrane. Dodavanjem premixa vitamin A se povećao od 10.000 do 25.000 i/j/kg i β-korotin od 6 do 12 mg/kg (tablice 2, 6, 11, 16, 23). Uzimanje hrane u tijeku nesivosti kretalo se od 280-360 g (dan) guska. Količina dodanog ethyl-estera (C30) u hrani kretala se od 8 do 36 mg/kg.

Rezultati su pokazali pozitivne učinke kombiniranog dodavanja 10.000 i/j. vitamina A s 24 mg ethyl-estera na 1 kg hrane na proizvodnju jaja što iznosi 2,5 do 5,5 gusćica više po nesilici u usporedbi sa samo 10.000 i/j. vitamina A. Dodavanjem 16 mg ethyl-estera + 10.000 i/j. vitamina A povećava se nesivost za 6,7% ili 2,8 gusćica više po guski dok je dodavanje 8 ppm bez učinka.

U makropokusu dobar je rezultat od 50,5 gusćica postignut u kontrolnoj grupi koja je dobivala hranu sa 20.000 i/j. vit. A. U tom trenutku ako je dodano 8 ppm ethyl-estera povećao se rezultat za 10,9%, odnosno 5,5 gusćica više po guski u periodu nesivosti.

Krvna slika varirala je u tijeku reprodukcijskog perioda i nije bilo utjecaja ethyl-estera na promjene vrijednosti u krvnoj slici te ukupnim bjelančevinama u krv. Utvrđeno je povećanje transferina, bolje vezanje željeza od 18 do 22% putem TIBC transferina. Manja saturacija transferina sa željezom pokazuje visoku otpornost gusaka koje su dobivale ethyl-ester. Nije utvrđena linearna ovisnost između β-karatina u serumu i količine dodanog ethyl-estera.

Dobiveni rezultati pokazali su da u industrijskoj proizvodnji krmnih smjesa za guske nesilice treba posebnu pažnju posvetiti dodavanju krmnim smjesama ethyl-estera ili karofil-žutog i β-karotina osobito u slučajevima kada se upotrebljavaju krmne smjese bez kuku ruza. Eliminacija zelene mase iz hranidbe gusaka mora se zamijeniti krmivima i dodacima koji sadrže visoke količine proridnih saantofilna naročito luteina, zeaxanthina i canthaxanthina.

Krmiva 34 (1992), Zagreb, 1, 33-55
Geese – typical herbivorous birds consume considerable amounts of soft plants and roots rich in variety of carotenoids, which does not comprise vit. A. The elimination of these feeds or reduction of these doses in intensive rearing system, as well as replacement of assortment of compounds in complete feed required reconstruction of natural xanthophyll contents, especially lutein, zeaxanthin and canthaxanthin in the diets (FLECHTER and HALLORAN, 1983; PAPPA et al., 1985; NEHRING and HOFFMANN, 1966). These substances, although easily absorbed, can not or can hardly be metabolized to vitamin A in the enterocytes of intestine walls of poultry. Also β-carotene is hardly converted into retinol, although it plays an important function in reproduction by stimulating progesteron production (PETHES et al., 1985; SCHWEIGERT, 1988).

Intensification of poultry production has brought about radical changes in rearing and feeding system of birds. Like other birds, geese in intensive rearing are fed with feed containing high cereals share. In the situation of maire deficiency, pastly replacement of maize rich in zeaxanthin by basley and other domestic cereals results in carotenoids shortage. Forages traditionally fed to geese in extensive rearing are replaced by dehydrated feeds of different nutritional value and carotenoid contents.

The opinions of specialists on intentionally increasing standard vit. A levels in complete feed from 10000 IU up to 20000 or even 30000 IU/kg are full of divergences (JAMROZ et al., 1979, 1985a).

The increased vit. A level in complete feed improves reproduction and hatchability, immunity of birds, lipids' metabolism, etc. (DAVIS and SHELL, 1983; HILL et al., 1961; SKLAN, 1983a, 1983b), whereas β-carotene given to layers and growing birds in different grade affected their performances (DAMRON et al., 1984; LORINCZ and LATOS, 1987; ŽARSKI et al., 1988). The mechanism of β-carotene conversion to vit. A in animals is well-known (BRUBACHER, 1975; GANGULY and SASTRY, 1985; SCHIEDT et al., 1985; SCHIEDT, 1988, 1990), but so far no data have been reported on geese, the birds naturally fed on green forages high in carotenoids.

Seven years ago, bearing in mind the peculiarity and significance of this problem in geese feeding, a research team at the Department of Animal Nutrition and Feed Management, Agricultural University in Wrocław and Experimental Station at the Institute of Zootchnical in Koluda Wielka undertaken the studies on optimal vit. A doses and carotenoid contents in the feed destined for reproductive geese.

Since the components of the complete feed manufactured at present are deficient in natural di-hydroxyxarotenoids, they can be supplemented with synthetic xanthophylls or β-carotene. Ethyl ester of β-apo-carotenic acid (C_{30}) is available on market as 10% Carophyll Yellow premix (Hoffman La Roche). This substances occurring in colourful feathers of birds, citrus fruit and green forages, affects pigmentation of poultry carcass and table eggs (JANKY and HARMs, 1983; KARUSZAJEEVA et al., 1984; KOCI et al., 1974; PAPPA et al., 1985; STREIFF, 1970; TIRANO et al., 1986; TYCZKOWSKI and HAMILTON, 1986a, i b) and for this reason it was used in feeding the reproductive geese assuming that its somatic, vitamin-similar action could improve the birds performances.

This paper is a synthesis of long-term studies carried out by the author and her co-operators in the years 1984-1989 (JAMROZ et al., 1985b, 1987, 1990a, b).

**MATERIAL AND METHODS**

In total, 5 experiments were carried out; experiments I-IV were conducted on 280 geese of White Italian breed in each and experiment V was performed on 1820 birds. The subgroups consisted of 30-32 geese and 6-8 ganders, one- and two- year old. Each feeding group consisted of 3-4 replications. During the egg production the light period was provided for 8 hours a day.

The birds were divided into the experimental groups in the middle of December and the laying period was due to begin in the second half of January. The studies commenced when the first egg was laid and were finished on till the end of June.

During the entire experimental period the number and fertility and hatchability, feed intake, mortality and its causes, from 20-23 settings, were determined.

In the laying period the birds were fed by complete feed containing 10% of dehydrated grass and small amounts of maize (or without maize) (Tables 1, 5, 10, 15, 22). The concentration of crude protein was 15,8% in experiment I and varied from 13,3 to 13,8% in the remaining experiments. Standard vit. A dose was constant i.e. 10.000 IU/kg of feed.

The birds were given supplement Polfasol A in order to increase vit. A level from 10.000 to 25.000 IU/kg. The quantity of applied ethyl-ester (C_{30}) in feed ranged from 8 to 36 mg/kg and β-carotene from 6 to 12 mg/kg (Tables 2, 6, 11, 16, 23). Feed intake during the laying period ranged from 280 to 360 g/day bird.
In the months March, May and June, i.e. from peak till reduced egg production 8-10 eggs were randomly selected from each group for the determinations which included: β-carotene, retinol and ethyl-ester (C30) contents of yolk by the method of liquid chromatography on the columns filled with Li-Chrosorb Si 60 um, the moving phase was composed of the mixture of heptane and n-octanol (ratio 99,6:0,4) at the flow rate of 1 ml/min. The examined compounds were detected spectrophotometrically at wavelength of 298 um.

Apart from the geese performance, the authors also focused their attention to the health of birds and their resistance to diseases, since a favorable effect of ethyl-ester (C30) supplementation on the health of geese had been observed (JAMROZ et al., 1985b, 1987, 1990a, b).

The blood for biochemical and morphological studies was collected from the wing vein of 6 birds in each trial group, three times during the laying period; thus the studies included 96 birds. The determinations in full blood comprised:

- Ht-index using a microhematocrit Unipan 316 centrifuge, morphotic elements by the Natt-Harrick method, leucogram by the Pappenheim method.
- The blood serum determinations included crude protein contents by biuret method, protein fractions by electrophoresis, transferrin using a radial immunodiffusion test made by «Mega» Biopreparators. Fe and total iron binding capacity (TIBC) after saturation with Fe compounds using a biochemical diagnostic test of POCCh Gliwice, reserve iron binding capacity (from the formula TIBC-serum Fe), transferrin saturation with Fe (serum Fe / TIBC × 100).
- Cu²⁺ (using a Lachema diagnostic test), ceruloplasmine (radial immunodiffusion test of f. Mega), β-carotene and retinol contents (liquid chromatography, aminotransferase activity; AspAT and ALAT by the Reitman and Frankel method using chemotests of POCCh Gliwice).

The data obtained in the morphological and biochemical studies were analyzed statistically using a variance analysis and multipical Duncan's test.

**RESULTS AND DISCUSSION**

The economical system of geese feeding i.e. reduction of protein contents in the feed from standard 16% to 13,3-13,8% and dailylight program reduced to 8 hours, consequently resulted in very high egg production, i.e. 58,0 (experiment I); 69,9 (II); 67,0 (III) 66,1 (IV) and 63,3 (V) eggs per layer. Specially high egg production was recorded in experiment II in which the number of eggs per layer averaged 71,0 (Tables 2, 7, 12, 16, 23).

The increase vit. A content in complete feed from standard 10.000 to 25.000 I.U./kg, did not improve the egg production, while combined administration of vit. A (10.000 I.U.) and ethyl-ester (C30) (24 mg/kg of feed) resulted in 4,7 (I); 2,8 (II) and 5,5% (III) increase in the number of eggs. However, the number of eggs recorded in group IV was only 2% lower than in the control. On the other hand, the increased vit. A content (20.000 I.U./kg) and low ethyl-ester concentration (8 ppm) improved egg production by 3,6% in comparison with the control.

The geese eggs weight did not show any differences to vit. A or ethyl ester (C30) supplementation.

Ethyl-ester C30 supplement markedly reduced the losses in the consecutive cycles of egg hatching (Tables 3, 8, 13, 17, 23) substantially enhanced an important reproductive rate – the number of healthy goslings from a layer. Combined administration of vit. A (10.000 I.U./kg) and ethyl-ester (24 mg/kg of feed) resulted in 6% (I); 3% (III) and 17,7 (IV) increase in the number of goslings as compared with the control group. In experiment V (20.000 I.U. of vit. A + 8 mg of ethyl-ester C30/kg) the increase reached 10,9%. These data are worth noting because the number of goslings from a layer was 43, 45, 46, 49 and 56 in each experiment. Presented results therefore suggest that not only vit. A supplementation but ethyl-ester C30 as well as natural carotenoids affect the viability of embryos (KOET-SEVELD, 1961), and consequently the number of goslings per layer.

The observations noted for all the experimental years prove that the geese given ethyl-ester C30 went through the laying season, so exhausting for their organisms, in very good health condition; they were active and had good appetite. No losses except for some accidental causes, were noted in females and no symptoms of clinical Neisse ria sp. were observed in ganders, though this is a serious problem in geese breeding (CHIFRA and PETHES, 1987).

The appearance of the goslings from mothers fed ethyl-ester supplemented mixtures was very appealing; their beaks and feed were bright orange, besides, they were very active and lively.

These explicit, though subjective observations encouraged the authors to conduct biochemical and morphological studies on geese blood in order to determine the indices characterizing the birds’ health and their immune system.

It was not evidence to indicate that the morphotic changes in the geese blood were effected by the experimental factors (Table 18). The Ht-index dropped markedly (P<0,01) after the laying peak. It could be suggested that its revival at the end of the laying season was due to other no- experimental factors and resulted by physiological characteristic of this period. Ethyl-ester C30 slightly increased the Ht-index (3-4%) irrespectively of the dosage applied.

A slightly increased (4,5-5,9%) number of erythrocytes was detected in the blood of birds fed with concentrates supplemented with 8-24 ppm of ethyl-ester, whereas the smallest number was noted in the control group (P<0,05). The highest number of leucocytes was found in group II but
the values did not exceed the physiological standards. The numbers of leukocytes increased significantly after 5 months of laying.

The leucogram of the laying geese did not show any significant changes due to ethyl-ester supplementation, although in the course of the laying season a decreased percentage of basophils (P<0.01), eosinophils and neutrophils was noted together with an increasing amount of monocytes. The percentage of neutrophils was rising at the end of the laying season. The lymphocytes increased markedly during the laying peak.

Total protein content of the blood serum was found within the range of 62 to 67 g/l, albumin ranged from 32 to 35 g/l, globulin 30 g, and ζ-globulin about 10 g/l (Table 19). No significant differences in geese serum protein concentration (excluding albumin) were observed in any of the feeding groups. After 2 months laying in the birds was exhibited elevated protein concentration in blood serum, but in the end of laying period it was significant decline (P<0.01).

Iron concentration and TIBC (transferrin) increased (P<0.01) after 1-2 months of laying, but the differences between the groups indicate a marked effect of ethyl-ester supplementation on biochemical blood indices (Table 20); serum TIBC was 6-8% higher in geese fed with ethyl-ester supplemented mixtures. The reserve iron binding capacity was significantly higher (18-22%) in the ethyl-ester supplemented geese (P<0.01) while the highest transferrin saturation with iron was observed in the control geese (P<0.05). As the laying period went, the higher was the numerical value characterizing this index in geese.

Variations of copper and ceruloplasmin serum contents did not suggest a definite relationship between amount of ethyl-ester supplementation and this biochemical indices. The variations were only due to the stage of egg production. The highest Cu²⁺ and ceruloplasmin level in blood serum were noted in birds of group IV (+8 ppm of ethyl-ester).

The biological function of transferrin synthetized in hepatocytes connected with iron transportation is wider, as it plays anti-microbial role in animals' blood. The inhibitory effect of transferrin on microbial growth is more pronounced if its saturation with iron is slight (GEHRKE, 1989).

Reduced concentration of free iron ions, increased transferrin TIBC and reduced degree of its saturation with Fe²⁺ indicated better immunity of birds from the ethyl-ester supplemented groups in comparison with the control. This was also confirmed by higher ceruloplasmin content of geese blood in those groups. The elevated ethyl-ester doses increased the reserve iron binding capacity linearly, but decreased the degree of transferrin saturation with iron. The changes in Cu and ceruloplasmin level were irregular.

AspAT and AIAT activity in blood serum was similar in all experimental groups, although AspAT was reduced (P<0.01) in the fifth month of egg production. Neither the presence of ethyl-ester in concentrates nor its quantity affected aminotransferase activity.

Combined vit. A and ethyl-ester C₃₀ supplementation did not affect the concentration of these substances in egg yolk (Table 4). However, the vit. A content of yolk increased when ethyl-ester was added to the feedstuff. Great individual variation of the discussed indices and the changes of their concentration in egg yolk during the egg production period (Tables 9,14) did not explain the relationship between the quantity of this biological active substance and retinol content of yolk.

Ethyl-ester supplementation affected significantly (P<0.01 and P<0.05) β-carotene content of the blood serum (Table 21). The linear increase in β-carotene, proportional to the ethyl-ester dose was the highest in blood serum of the geese supplemented 24 ppm of ethyl-ester, but it decreased with the decreasing supplementation. The variation in β-carotene content of blood serum were great and ranged from 0.33 to 8.72 mmol/l. Retinol content of serum was more stable and averaged 3.20 mmol/l in all groups, excluding group II in which it was 14% lower.

### References

The results of experiments indicate positive effect of combined application of 10,000 I.U. vitamin A with 24 mg ethyl-ester per 1 kg of feed (on air dry matter basis) on egg production which resulted in 2,5-5,5 goslings more from layer as compared with birds given 10,000 I.U. vit. A/kg only. The dose of 16 ppm ethyl-ester + 10,000 I.U. vit. A enhanced productive results by 6,7% (2,8 goslings from geese) while the addition of 8 ppm appeared to be ineffective.

In the field trial good productive result - 50,5 goslings from layer, was noted in the control group fed concentrate mixture contained 20,000 I.U. of vit. A/kg. In these treatment addition of 8 ppm ethyl-ester increased results by further 10,9% i.e. by 5,5 from one geese and more stable run of laying period was observed. (Fig. 1).

The blood morphology indices varied during reproductive season and no effect of ethyl-ester addition was noted. Similarly, level of total protein and its fractions were not influenced by applied supplements and were related to the stage of laying period only.

The higher level of transferrins, better iron binding capacity by TIBC transferrins (by 18-22%), lower transferrin saturation with Fe indicated of higher resistance in geese given ethyl-ester. This is in agreement with findings of MAZURKIEWICZ et al. (1990) who found the increase of cell resistance in cocks fed concentrate mixtures with high level of vit. A supplemented by carotenoids. The important role of retinol in the immune system was earlier shown by DAVIS and SELL (1983).

No explanation can be given for linear relationship between β-caroten in the serum and amount of supplemented ethyl-ester. In the available literature there is no evidence for conversion to β-caroten in geese, however its cumulation in the serum could be affected by ethyl-ester (GANGULY and SASTRY, 1985). No similar relation have been observed for retinol concentration in the serum. A high pro-vitamin activity (1,0,40-0,44 in re-count of molar activity) of ethyl-ester, similar to that of vit. A acetat, indicated results of WEISER et al. (1989), however these findings concerned rats - all phagig mammals. In herbivorous birds another activity of ethyl-ester C_{30} can be expected.
