MODELING AND OPTIMIZATION OF FACE MILLING PROCESS PARAMETERS FOR AISI 4140 STEEL

Gokhan BASAR, Hediye KIRLI AKIN, Funda KAHRAMAN, Yusuf FEDAI

Abstract: In this study, the effect of cutting parameters such as the depth of cut, feed rate, cutting speed and the number of inserts on surface roughness were investigated in the milling of the AISI 4140 steel. The optimal control factors for surface quality were detected by using the Taguchi technique. Experimental trials were designed according to the Taguchi L_{21} (21x3) orthogonal array. The statistical effects of control factors on surface roughness have been established by using the analysis of variance (ANOVA). Optimal cutting parameters were obtained by using the S/N ratio values. The ANOVA results showed that the effective factors were the number of inserts and the feed rate on surface roughness. However, the depth of cut and the cutting speed showed an insignificant effect. Additionally, the First-order and Second-order regression analysis were conducted to estimate the performance characteristics of the experiment. The acquired regression equation results matched with the surface roughness measurement results. The optimal performance characteristics were obtained as a 0.5 mm depth of cut, 0.08 mm/rev feed rate, 325 m/min cutting speed and 1 number of inserts by using the Taguchi method. Additionally, the confirmation test results indicated that the Taguchi method was very prosperous in the optimization of the machining parameters to obtain the minimum surface roughness in the milling of the AISI 4140 steel.

Keywords: AISI 4140 steel; milling; regression analysis; surface roughness; Taguchi method; variance analysis

1 INTRODUCTION

The metal cutting process is defined to remove the unwanted material from the metal parts by using a cutting tool. Materials were moved by a conventional chip forming process such as milling, drilling, boring, turning in the manufacturing industry [1, 2]. The milling process is one of the most significant metal removal processes in the traditional metal cutting operations.

The surface quality is a significant factor to appraise the productivity of both the mechanical parts and machined components. Hence, it is a very crucial measurement of the product quality. Surface quality is usually concerned with surface roughness. The surface roughness of the machine elements is understood to have a prominent influence on certain properties such as increasing the tribological properties of materials, wear resistance, fatigue strength, heat conduction, electrical conductivity, corrosion resistance and aesthetic appearance. However, it can also lead to increased production costs [3-5].

Nowadays, there have been numerous study advancements in the surface roughness modeling and the optimization of the performance of the manufacturing technologies. In order to produce a desired surface finish and to reach the greatest productivity of machining, cutting parameters should be chosen appropriately [6].

Regarding past research, surface roughness was examined in distinct research studies in which the experimental results, the mathematical models and statistical methods were assimilated. For instance, Filho et al. [7] studied the experimental numerical model of roughness in the finishing face milling of the AISI 4140 hardened steel. They applied the central composite design to optimize the cutting factors such as the cutting speed, feed and cutting depth in the end milling when machining the AISI 4140 steel with a CBN (cubic boron nitride) tool. The feed per tooth had a statistical prominent factor affecting the average surface roughness in the face milling. Ventura et al. [8] researched the machinability of the hardened AISI 4140 steel when turning with varied micro geometries. It is shown that the cutting edge micro geometry largely influences the feed and passive force components, whereas the cutting force, specific energy and cutting temperature are not strongly changed. Sales et al. [9] conducted the external vegetable oil-based minimum quantity cutting fluid in the milling of the AISI 4140 steel with a TiAlN coated cemented carbide insert. The minimum quantity fluid application supplied usually decreases the tool wear rate and as a result enhances tool life. Ozek et al. [10] used the Fuzzy logic to investigate the effect of the machining factors on the plasma arc machining process of the AISI 4140 steel. The fuzzy logic model was developed to predict the surface roughness. Results showed that the cutting speed had the statistical importance on the performance characteristic, whereas the plasma arc current had the least importance. Kvak and Cetin [11] performed the Taguchi method and regression analysis to identify the machinability of the 15-5 PH Stainless steel with the PVD TiAIN-AICrO and CVD TiCN-Al2O3-TiN-coated carbide-cutting-tool inserts. It was observed that feed rate was a maximum contribution to surface roughness, whereas the depth of cut was a maximum contribution to the cutting force. Sarikaya et al. [12] researched the effects of machining factors such as the cutting speed, feed rate and the number of cutting inserts on surface roughness and tool life in the face milling process of the AISI D3 steel with carbide coated inserts by using the Taguchi design technique. The experimental results presented that the number of cutting inserts was the most significant parameter affecting surface roughness, while cutting speed was the most significant parameter affecting tool life. Motorcu et al. [13] machined the AISI 4140 steel with a tungsten carbide cutting tool on a lathe.
They investigated the effect of the depth of cut, the cutting speed and feed rate on the formation on surface roughness, the tool temperature and the tool-chip interface temperature by using the Taguchi method. Predictive models were developed to estimate the output performance characteristics by using the regression analysis. Ekici et al. [14] examined effects of wire speed, pulse on time and pulse off time on the material removal rate and surface roughness during the wire electrical discharge machining (WEDM) operation of the Al/B4C/Gr reinforced hybrid material by using the Taguchi technique and Response Surface Methodology. It was eventually detected that the most important parameter for the material removal rate is the wire speed, while for surface roughness the most dominant parameter is pulse on time. Gupta et al. [15] studied the effects of machining parameters such as the cutting speed, feed rate and distinct cooling conditions on a cutting force and surface roughness in the turning of the AISI 4340 steel by using the uncoated carbide insert. The Taguchi technique and the utility concept were used for the determination of the optimal performance characteristics simultaneously. They found that the cooling condition has a dominant effect on the performance characteristics. Kivak [16] researched the effects of machining parameters (cutting tools, cutting speed and feed rate) on surface roughness and flank wear by the aid of the Taguchi design technique in the dry milling of Hadfield steel. It was determined that in surface roughness, the most effective parameter is feed rate, while for flank wear, the cutting speed was the most powerful parameter. Ekici et al. [17] explored the influences of the cutting factors (wire tension, reinforcement percentage, wire speed, pulse-on time and pulse-off time) on the material removal rate and surface roughness in the WEDM process of the Al/B4C composites produced via the hot pressing method by using the Taguchi method. The variance analysis results indicated that the dominant factor for the material removal rate is wire speed, while for surface roughness the most effective factor is pulse on time.

In this paper, the modeling and optimization of cutting parameters on surface roughness in the milling process of the AISI 4140 steel were researched by using the Taguchi technique and regression analysis. The furthest machining factors on surface roughness were conducted by using the analysis of the signal to noise (S/N) ratio and analysis of variance (ANOVA). The predictive equations were descended from the regression analysis to acquire the optimal surface roughness as a function of the milling parameters. Hence, the experimental and regression analysis results were compared with each other.

2 MATERIALS AND METHODS

The milling tests were conducted in dry cutting conditions by using a SPINNER MVC1000 model CNC milling machine equipped with a maximum spindle speed of 10000 rpm. The experimental set up is displayed in Fig. 1. The dimensions of the workpiece were 260 × 150 × 25 mm. Before the tests started, the steel bulks were ground to remove the reverse effects of any surface disturbance. The milling tests were carried out at two depths of cut (0.5 and 1 mm), three feeds (0.08, 0.12 and 0.16 mm/rev), three cutting speeds (175, 250 and 325 m/min) and three numbers of cutting inserts (1, 2 and 3 piece). The milling process was applied by using a R 390-020B20-11M tool holder and a TiAlN+TiN, PVD-coated, R 390-11 T308M-PM 1030 solid carbide insert. In the milling tests, only one insert was used to minimize the effect of the tool tip run out on tool wear. The quality of a cutting surface is generally identified by the surface roughness and it is measured offline after the surface is cutting. After the milling tests, the average surface roughness (Ra) of workpieces was measured by the MITUTOYO SJ-400 transportable surface roughness tester. The cut off length and evaluation length were constant at 0.8 mm and 4 mm respectively. The measurement of surface roughness was carried out on a machined surface from three distinct points. The average value of the measurements was taken into evaluation to analyze the surface roughness attitude. Surface roughness measurements are illustrated in Fig. 2.
Taguchi L18 mixed orthogonal design matrix was conducted for performing the experiments.

3 ANALYSIS AND EVALUATION OF EXPERIMENTAL RESULTS

3.1 Taguchi Analysis

The Taguchi method is a strong design tool and it is extensively used in engineering problems. Furthermore, it considerably decreases the quantity of experiments using the orthogonal design matrix and reduces the influence of factors that cannot be controlled. Moreover, it ensures an easy, productive and systematical approach to indicating the optimal machining conditions for the manufacturing industry [18, 19]. The Taguchi technique uses a loss function to compute the deviation between the test values and the willed values. This loss function is also turned into a signal–noise (S/N) ratio [20].

where \( y_i \) is the \( i^{th} \) measure of the actual test data in a run and \( n \) is the number of measurement in each experimental test [21].

Optimal level

In this paper, ANOVA was employed to analyze the influence of the depth of cut, feed rate, cutting speed and number of inserts on surface roughness. The objective of ANOVA is to establish how the process parameters affect the quality characteristics [22, 23]. This analysis was conducted for a confidence level of 95%. The surface roughness is conducted to detect the utmost effect factor in the machining parameters by ANOVA. In the machining process, cutting parameters have an important effect in the experimental results. The ANOVA results for surface roughness are presented in Table 4. The number of inserts was determined as an important factor since its p value is less than 0.05.

The smaller-is-better, the-nominal-best and the larger-is-better approaches are established considering the results of the S/N ratio. The objective of this research was to reduce the surface roughness. For this reason, the smaller-the-better quality characteristic was used as presented in the Eq. (1) and listed in Tab. 2. The average of the S/N ratio for each level of the machining parameters is calculated and given in Tab. 3. The graph of the mean of the S/N ratios versus the factor levels is shown in Fig. 3.

\[
S = -10 \log \left( \frac{1}{n} \sum_{i=1}^{n} y_i \right).
\]
with a percentage contribution of 62.48%. Moreover, the feed rate had a considerable influence on surface roughness with a percentage contribution of 21.16%. However, the depth of cut and the cutting speed proved to be an insignificant factor on surface roughness.

The result obviously indicates the influence of the number of inserts on surface roughness in milling the AISI 4140 steel whose vibration produced a sophisticated frequency between the cutting tool and the workpiece with the enhancement number of the cutting insert. The other variable that has an effect on Ra is the feed rate with 21.96%. It is clear that increasing of the feed rate increases the chip volume removed per unit time [12, 24].

First-order regression equation:

\[
Ra = -0.539 + 0.041ap + 4.05f - 0.00382V + 0.2760N
\]

\[
R^2 = 80.53
\]

Second-order regression equation:

\[
Ra = 1.665 + 0.100ap - 15.86f - 0.00231V - 0.725N + 40f^2 + 0.00003V^2 + 0.1026N^2 + 2.22ap \cdot f - 0.00054ap \cdot V - 0.066ap \cdot N + 0.00292f \cdot V + 4.094f \cdot N + 0.000583V \cdot N
\]

\[
R^2 = 98.95
\]

3.2 Regression Analysis

Regression analysis is performed for the modeling and analyzing of several variables, which have the relationship between a dependent variable and one or more independent variables [25]. In this paper, the dependent variable is surface roughness (Ra), while the independent variables are the depth of cut (ap), feed rate (f), cutting speed (V) and number of inserts (N). The experimental test results were utilized to obtain the mathematical models by using the first-order and second-order model. The predictive equations which were acquired by using the first-order and second-order regression model of surface roughness are given below.

The comparison of the experimental results and the predicted values which were obtained by the first-order and second-order regression model are given in Fig. 4. The correlation coefficients (\(R^2\)) of the first-order and second-
order regression equations that advanced for the predictive surface roughness were computed as \( R^2 = 80.53\% \) and \( R^2 = 98.95\% \), respectively.

Fig. 5 shows the 3D surface graphs, which provided a Minitab 17 software for surface roughness. The relationship between the feed rate \( f \) and number of inserts \( N \) is shown in Fig. 5(a), the relationship between the cutting speed \( V \) and feed rate \( f \) is shown in Fig. 5(b) and the relationship between the feed rate \( f \) and the depth of cut \( ap \) is shown in Fig. 5(c). It reveals that surface roughness decreases with a reduced feed rate and with a diminished number of inserts in Fig. 5(a). Hence, a minimum level of the feed rate and a minimum number of inserts is required for minimum surface roughness. It appears that surface roughness decreases with a slight change in the cutting speed \( V \) and with a diminished feed rate \( f \) in Fig. 5(b). It shows that surface roughness decreases with a minimized feed rate \( f \) and a slightly changed depth of cut \( ap \) in Fig. 5(c).

### 3.3 Confirmation Test

Before the optimum level of control factors is chosen, the last step of the Taguchi technique approach is to estimate and confirm the development of the control factors by using the optimum level of control factors.

Factors that will be utilized to achieve the optimal \( Ra \) value and their levels are detected as \( ap/f/V/N \) with the aid of Tab. 3 and Fig. 3. The minimum \( Ra \) and its \( S/N \) ratio that can be acquired considering these levels were computed by using the Eqs. (4) and (5). The \( Ra \) value and its \( S/N \) ratio were established as 0.125 \( \mu m \) and 18.0657 dB respectively.

\[
\eta_G = \eta_m + \sum_{j=1}^q (\bar{\eta}_i - \eta_m) \tag{4}
\]

\[
Ra_{\text{opt}} = 10^{\frac{S/N}{20}} \tag{5}
\]

where \( \eta_G \) is the \( S/N \) ratio computed at the optimum levels (dB), \( \eta_m \) is the overall average of the \( S/N \) ratio, \( \bar{\eta}_i \) is the average \( S/N \) ratio at the optimum level, and \( q \) is the count of the control factors that remarkably influence the performance characteristic. Then, \( Ra_{\text{opt}} \) is computed for the \( Ra \) value [26]. The confirmation test results were demonstrated by using the optimal control factors of surface roughness in Tab. 5.

<table>
<thead>
<tr>
<th>Table 5 Confirmation test results for surface roughness</th>
</tr>
</thead>
<tbody>
<tr>
<td>Initial machining factor</td>
</tr>
<tr>
<td>Level ( ap/f/V/N )</td>
</tr>
<tr>
<td>Ra</td>
</tr>
<tr>
<td>( S/N ) ratio (dB)</td>
</tr>
<tr>
<td>Improvement of the ( S/N ) ratio 13.656 dB</td>
</tr>
</tbody>
</table>

A comparison of the experimental results and the predicted results obtained with the Taguchi method is shown. When the predicted value of \( S/N \) (18.0657 dB) was compared with the actual value of \( S/N \) (17.265 dB) in the optimum level of control factors, a relatively good agreement was found. The enhancement of the \( S/N \) ratio from the initial machining parameters to the optimum machining parameters is 13.656 dB. The confirmation test results noticed that the surface roughness decreased 4.81 times.

### 4 CONCLUSIONS

In this research, the effect of the feed rate, cutting speed, depth of cut and number of inserts on the surface roughness in the milling process of the AISI 4140 steel with TiAIN+TiN were analyzed. The PVD coated carbide insert was performed and researched by using the Taguchi design technique. The main results were as follows:

- To optimize surface roughness Taguchi’s \( S/N \) value was employed. The effect of machining parameters on the performance characteristic was investigated by the analysis of variance. From signal to noise ratio analysis was employed. It was concluded that the optimum values for minimizing surface roughness were 0.5 mm for the depth of cut, 0.08 mm/rev for the feed rate. 325 m/min for the cutting speed and 1 for the number of inserts.
- The acquired results showed that the number of inserts was detected to be an effective factor among the controllable factors on surface roughness, followed by feed rate. However, the depth of cut and cutting speed proved to have an insignificant effect.
- The predictive models of surface roughness were also established by using the regression analysis.
- It was indicated that the experimental and regression analysis results could be effectively used for the estimation of surface roughness in the milling process of the AISI 4140 steel.
- The Taguchi design method was an effective method for the modeling and optimizing of surface roughness in the milling process.
- The development of surface roughness from the initial machining parameters to the optimal machining parameter is about 481%.
- In the manufacturing engineering applications, the Taguchi design technique and regression analysis were able to supply the minimum cost and time.
