ABSTRACT:
Hematopoietic Stem Cell Transplantation (HSCT) has been widely used for decades as the most effective treatment of several malignant and non-malignant hematological diseases. Among many complications with occurrence after HSCT procedure, reproductive issues are often neglected although these can adversely affect the patient quality of life. The most common gynecological complications after HSCT include: ovarian insufficiency, increased risk of cervical atypia and carcinoma, thrombocytopenia-associated menorrhagia, genital involvement of graft versus host disease, osteoporosis, fertility and pregnancy issues etc. Due to their relevance to the patients and constant growing of life expectancy of women after HSCT it is of huge importance to diagnose and treat reproductive complications after the transplantation procedure by multidisciplinary approach.

KEYWORDS: Allogeneic hematopoietic cells transplantation, reproductive complications, ovarian insufficiency

SAŽETAK:
Utjecaj alogene transplantiacije hematopoetskih stanica na reproduktivno zdravlje žena: kratki osvrt

Transplantacija krivotvornih matičnih stanica (engl. HSCT) široko se koristi desetljećima kao najčinjeničniji tretman nekoliko zloćudnih i nemalnjenih hematoloških bolesti. Među mnogim komplikacijama koje se javljaju nakon HSCT postupka, reproduktivna su pitanja često zanemarena, iako ona mogu negativno utjecati na kvalitetu života pacijenta. Najčešće ginekološke komplikacije nakon HSCT-a uključuju: insuficijenciju jajnika, povećani rizik od atipije i karcinoma cerviksa, menoragije, povezane s trombocitopenijom, zahvaćenost transplantata u odnosu na domaćina, osteoporozu, plodnost i trudnoću itd. Zbog njihove važnosti za pacijente i konstantne rast očekivanog života žena nakon HSCT-a od velike je važnosti dijagnosticirati i liječiti reproduktivne komplikacije nakon postupka transplantacije multidisciplinarnim pristupom.

KLJUČNE RIJEČI: Alogena transplantacija krivotvornih stanica, reproduktivne komplikacije, insuficijencija jajnika
INTRODUCTION
Allogeneic hematopoietic cell transplantation (HCT) is a widely used medical procedure for treatment of a different hematologic diseases. Around 85% of HCT is performed for curing malignant diseases, such as acute and chronic leukemias and lymphomas, while the rest of the procedures is used for diverse non-malignant states like aplastic anemia or immunodeficiency. Progress in this medical field regarding patient and donor selection, stem cell isolations, supportive care, prevention of different complications and decreased-toxicity of preparative procedures resulted in expansions of the indications for HCT and number of patients treated by this method. On the other hand, the numbers of long-term survivors following hematopoietic stem cell transplantation have been notably increasing in last decade. In modern medicine it became mandatory to consider not only the survival rate, but also the quality of life of patients after HCT. Approximately 40% of these patients are female and the aspect of their gynecological health could not be neglected. Complications of HCT vary upon of many factors such as preparation procedures before the transplantation, age of the patient, comorbidity, primer disease, time of transplantation and many other clinical characteristics. Complications of HCT can be divided into two main groups upon the onset time: early complications that develop in the first 100 days after the procedure and late that occur after that time. Early complications include: hemorrhagic cystitis, veno-occlusive disease, thrombotic microangiopathy and different respiratory complications. Infections that could be bacterial, viral and fungal could also involve all organs and systems and its prevention and treatment is of major concern for survival and life quality. Graft versus host disease (GvHD) that could develop as an early and late complication is very serious event and among leading causes of death along with relapse of the underlying primary disease and infections. Late complications can involve almost every organ disturbing later life such as cataract, arrhythmia, osteoporosis, diabetes, dental problems etc. Female reproductive system has been shown to be highly predisposed to the effect of HCT procedure. These complications have later onset and include: premature menopause, genital type of GvHD, cervical carcinoma, human papilloma virus reactivation, vaginal infections and sexual dysfunctions. It is clear that allogeneic HCT has negative impact on fertility often causing premature ovarian insufficiency and infertility, and even complicating possible pregnancy. All the mentioned gynecological problems negatively impact the quality of women life after HCT which should be considered and prevented multidisciplinary.

In this review we will discuss the impact of allogeneic HCT on female reproductive system with special considerations on long-term consequences.

THE EFFECT OF ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION ON OVARIAN FUNCTION
It is well known that HCT procedure and its previous preparation management effect ovarian functions at several levels. This negative influence on ovaries impact the female well being, health and fertility demanding gynecologic care at several stages and collaboration between health professionals. The most important potential consequence of HCT procedure is ovarian insufficiency which is characterized by loss of ovarian function with hypergonadotropic hypogonadism, decreased uterine and ovarian volumes and most prominent symptom of secondary amenorrhea. Our results have also confirmed elevated levels of follicle stimulating hormone (FSH) and luteinizing hormone (LH) in women who underwent HCT as compared to controls. Ovarian insufficiency is most common complication affecting more than 90% of patients depending on age and therapeutical regimens. In our study all the patients were affected probably due to the advanced age since median age was 42 years. The exact mechanism of HCT impact on ovarian function has not yet been elucidated, although pretransplant conditioning regimen has been well appreciated. Indeed, conditioning regimens that include high-dose alkylate treatments associated or not with total body irradiation can severely damage the ovaries. On the other hand, reduced-intensity conditioning did not result in significant improvement of ovarian function pointing that other mechanism could be involved in the subject. It has been shown that even graft-versus-host disease could target granulosa cells of the ovarian follicles, thereby significantly reducing fertility and causing ovarian insufficiency. This explains why pharmacological GVHD prophylaxis could help in preserving fertility after HCT. In addition, long-lasting steroid treatment used in GvHD management can have additional negative impact on ovarian function.

Ovarian insufficiency is not always irreversible condition with younger age and higher estradiol levels being positive predictors of ovarian restoration. Advanced age is independent risk factor, with the age of 30 being consider as cut-off value for irreversible ovarian damage. Underlying disease has also influence on ovarian failure since it has been shown that acute lymphoblastic leukemia and lymphoma increase the risk of premature menopause. As expected allogeneic transplantation also increased the risk of ovarian damage as compared to autoimmune transplantation.

Since ovarian insufficiency is characterized by various symptoms of estrogen depletion, such as hot flushes, mood disorders, sleep disorders, etc, what negatively impact the quality of life it is important to prevent, diagnose and treat this disorder.

THE EFFECT OF ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION ON CERVIX
It is well known that immunocompromised women, including those after hematopoietic stem cell transplantation, have an...
increased risk of cervical cancer\textsuperscript{13}. Since this mainly squamous carcinoma develops in stepwise pattern, it is reasonable that different grade squamous intraepithelial lesions also occur with higher prevalence after HCT procedure\textsuperscript{15}. We have shown that less than 4\% of patients after HCT have normal results of cervical Papanicolaou smear as compared to 76\% in general population\textsuperscript{1}. Similar results have been published by Negri and coworkers who extended the surveillance of patients and have shown the regression of the changes in many cases\textsuperscript{14}. The addition of busulfan in chemotherapeutic regimens increased the number of abnormal cervical smears\textsuperscript{14}. As expected, allogeneic HCT increases cervical abnormalities as compared to autogenic HCT\textsuperscript{15}. Moreover, younger age and previous atypia in cervical Papanicolaou smears enhance the risk for post treatment abnormalities\textsuperscript{15}. Recent study introduced the term therapy-related atypia that has been shown in around 11\% of patients if cervical smear test was sampled within 100 days after HCT\textsuperscript{16}. These cytological changes mimic precancerous lesions, but cervical surgical procedure and human papilloma virus tests were all negative. Repeated sampling showed the regression of cytological changes pointing that clinical informations are of crucial importance for patient management. All abnormal tests were found in patients treated by busulfan-containing chemotherapy, while no changes were observed after total body irradiation or nonbusulfan-containing chemotherapy\textsuperscript{16}.

The pathogenesis of different cervical abnormalities include long-term chemotherapy, graft versus host disease and immunosuppressive therapy that all result in decrease cellular and humoral immunity. Although all these procedures have beneficial roles in transplant protection, they also predispose patients to different bacterial and viral infections, such as human papilloma viruses that are in the basis of all cancerous cervical changes. It is unclear whether newly found cytological abnormalities are the results of new infections or reactivations of latent HPV virus in the setting of immunosuppression\textsuperscript{17}. In addition, genital GVHD and unrelated HLA-matched donor were shown to be risk factors for developing cervical cytological abnormalities\textsuperscript{15}. Opposite from mild cervical cytologic abnormalities, Holowaty et al. have reported the risk of progression for moderate dysplasia was 16\% within 2 years and 25\% within 5 years (18). The risk for cervical carcinoma was significant within 2 years after the abnormal Papanicolaou smear test\textsuperscript{15}. Moreover, it has been shown that patients after HCT have double risk for occurrence of solid tumors in a period of 10 years as compared to general population with GVHD being an independent risk factor for squamous cell carcinoma\textsuperscript{18}.

**OTHER REPRODUCTIVE ISSUES AFTER HEMATOPOIETIC CELL TRANSPLANTATION**

It is well known that different modalities of treatment used in procedure of HCT effectively destroy the patient's bone marrow with subsequent pancytopenia which can result in severe morbidity. One aspect of this condition is thrombocytopenia which can induce thrombocytopenia-associated menorrhagia, particularly in women who had experienced irregular vaginal bleeding before the HSCT\textsuperscript{20}. On the other hand, it has been shown that there is no correlation between severe menorrhagia and a general bleeding predisposition in other body sites\textsuperscript{27}. Although thrombocytopenia-associated menorrhagia can affect up to 40\% of patients undergoing HCT and can severely affect the morbidity and life quality of those patients, there are only few publications on the most effective treatment of this condition\textsuperscript{21-23}. Beside the tranexamic acid that has been used for the treatment of menorrhagia of different origin, other effective treatment for thrombocytopenia-associated menorrhagia include gonadotropin-releasing hormone analogues and depo-medroxyprogesterone acetate\textsuperscript{21}. It is also advisable to perform initial pelvic sonogram to diagnose gynecologic disorders that can alleviate menorrhagia and to remove intrauterine device, since it can predispose for pelvic infections during a period of pancytopenia\textsuperscript{21}.

Chronic GVHD is a serious complication of HCT procedure that occur in 30\% to 50\% of transplants from human leukocyte antigens-matched siblings and 60\% to 70\% from matched unrelated donors\textsuperscript{14}. This condition usually develops over several weeks and months and involving inflammation, cell-mediated immunity, humoral immunity and fibrosis in its etiology\textsuperscript{25}. The most common affected organs are: skin, mouth, eyes, liver, and intestines. Genital tract is involved in around 25\% of patients with mostly vulvar disease manifested as erosions and fissures\textsuperscript{26}. Vulvar and vaginal scarring are less common complications that can result in vaginal obstructions and labial fusion\textsuperscript{27}. Patients with these complications usually complain of genital pain, burning, dysuria, swelling, soreness, dryness and dyspareunia. The most effective treatment include: local estrogen therapy, topical steroids and immunosuppressants with surgery in most severe cases of disturbed anatomy.

Osteoporosis is another potential complication in patients undergoing HCT due to the several mechanism. The most common causal mechanism is the lack of estrogens associated with ovarian insufficiency, lack of ovulation and consecutive amenorrhea\textsuperscript{28}. Other possible causes include different conditioning regimens, huge cytokine re-release at the time of transplant, long-lasting immunosuppressive therapy and impaired intake and metabolism of calcium and vitamin D. Since osteoporosis can severely impact patient’s morbidity and mortality, it is important to diagnose it and to start early treatment such as lifestyle modification, calcium and vitamin D supplementation, bisphosphonates and hormonal therapy\textsuperscript{29}. Due to the previously described ovarian insufficiency, fertility is severely impaired after allogeneic stem cell transplantation with estimated overall conception rate under 1\%\textsuperscript{30}. Several factors contribute to this low conception rate. The most important
negative factors are advanced age at the time of HCT and regimens that include busulfan. Nowadays, oncologic patients are interested in fertility preservation in general. There is a growing number of cases with successful procreation after malignancy including those using classical oocytes/eggs freezing procedure or novel strategies such as ovarian tissue freezing. It is clear that these techniques require multidisciplinary approach including oncologists, reproductive gynecologist, surgeons, and others.

**Conclusion**

Reproductive sequels are among most common complications after hematopoietic stem cell transplantation which negatively affect the quality of life both in short and long time periods after the procedure. On the other hand, these problems are often underestimated by professionals whose concern is more in overall survival and life-treating complications. Since due to the medical improvement life span after HCT is constantly growing, focus should be pointed to better recognition and treatment of different gynecological disorders enabling maximum reproductive health and procreation if possible. This should be a concern of different specialists ensuring better quality of life in patients after HCT procedure.
