Angle-Aware and Tone-Aware Luminosity Analysis for Paper Model Surface

Xiaozhou LI*, Mingming CUI, Xiaomeng HAN, Guangyuan WU, Jingjing LIU

Abstract: Luminosity contributes to the paper model surface perception. It has a significant impact on the perception of colour and details. The main purpose of this paper is to study the reflection luminosity of paper model surface which can be of complex or difficult shape surface. The final perception quality of a product, whether it is plain or 3D or other different shape, depends on the surface luminosity perceived by the receptor, such as eyes or measurement instruments. However, the number of parameters and limits of the paper model surface are enormous. It is a time-consuming work to select every parameter by a trial-and-error procedure. For a paper surface under the fixed lighting environment, the most important factors to decide the performance of perception are commonly viewing angles and surface tone. Therefore, the two related terms, perception angle and surface tone, were chosen to work in the analysis process. The final analysis, based on the initial conditions, enabled to predict the perception of paper model surface and to set the optimal perceived angels and tones. It still proposed the next step to model the perception of paper model surface of different shapes in a relatively short period.

Keywords: luminosity; paper model surface; perception angle; reflection spectral measurement; tone value

1 INTRODUCTION

Colour analysis of paper model product has been an extremely popular topic in many research areas including colour reproduction, image processing, 3D printing, human skin colour measurement and analysis, etc. For example, luminosity of skin surface, which is similar to 3D paper model surface, is obtained using special under different viewing angles [1]. In addition, translucency is also added to help improving 3D printing colour quality [2]. The difference is that paper model product is always opaque usually. Kubelka-Munk model is also used to reproduce human skin colour, though it is more common in silk colouration research area [3]. And there are some reports to present colour measurement method for auto surface colour [4]. Reference focused on processes and colour quality evaluation of colour 3D printing [5]. However, with the development of 3D paper printer, there always lacks a method to predict, measure or evaluate the luminosity of paper product, which is essentially different from the methods used in plain printing colour perception, i.e., 2D colour printing on paper [6]. Luminosity depends on the field of research, i.e., there are different meanings in different area. It means the ratio of luminous flux to radiant flux at the same wavelength in physics while it would mean the ratio of a star radiating energy in stereo directions [7]. It also can be stimulus value in printing colour reproduction related transparency which has fewer relations with surface luminance perception [10]. It showed that it is easier to use plain surface to simulate the perception of stereoscopic paper model surface. The phenomenon was described easily using the plain paper surface with various angles and tone values together, though there are some differences between stereoscopic paper model and plain paper model. As a result, it is important to evaluate how luminosity changes the appearance of the paper model products. Perception point positions and viewing angles referring to the origin in Cartesian Coordinate System were chosen to measure and analyse the appearance in this paper. The spatial configuration of perceived point and area is shown in Fig. 1 and Fig. 2.

In Fig. 1a, if the position $P$ changes to $P'$, the incidence angle $\alpha_i$ will change to $\beta_i$, which results in reflectance angle $\alpha_r$ changing to $\beta_r$. In other words, the perceive angle will always change with incidence angle. As a result, the reflect light amount will change and the perception is different for the different $P$ positions. However, for the same position $P$, in Fig. 1b, the reflectance angle $\theta$ will always change with the incidence angle $\theta_i$. In actual situation, the light source is always set in a fixed position, while the surface is set at a designated angle to the perception position. In Fig.1b, the light source position and the paper surface $P'$ are stable to the whole viewing conditions while the perceived angle between the perceptor and $P'$ is variable.

For stereoscopic paper model objects, the actual perception conditions always perform as in Fig. 1 and Fig. 2. In Fig. 2, the reflect light, $d_s$, from the area surface, $d_s$, is always perceived in a solid angle, $d\Omega$. For the same
viewing conditions the appearance will be different for the combination of viewing conditions. It is also described as the directional reflectance characteristics [11-14], which has a famous theory, i.e., BRDF, as follows:

\[
f_r(\theta_i, \phi_i, \theta_r, \phi_r) = \frac{dL_r(\theta_i, \phi_i, \theta_r, \phi_r)}{dE_i(\theta_i, \phi_i)}
\]  (1)

where, \(L_r\) is reflected radiance, \(\theta\) and \(\phi\) indicate the direction, \(i\) indicates quantities associated with incident, \(r\) indicates quantities associated with reflected, \(E_i\) indicates incident irradiance and \(d\) indicates a differential quantity. Because the paper surface is always rough even when printed with inks, the reflected radiance is not scattered into one direction but into different directions. This is shown in Fig. 3.

In Fig. 3a, the paper surface or paper product surface with ink is always rough. It is covered with ink dots of different sizes. The light with the surface is of diffuse reflection, just like Fig. 3b and Fig. 3c. It shows the light perception composition from the paper product surface. With Fig. 1 and Fig. 2, we could find that it is always difficult to evaluate the stereoscopic paper product surface luminosity and colour effectively using traditional method. Consequently, the colour measure method and prediction method are different from the methods used in 2D or plain printing. And it is also not easy to perceive or predict the luminosity, then colour, of the paper product under a given viewing situation. It is necessary to do the research on the perception of stereoscopic paper product to help solving the problems above.

The luminosity of paper product always changes with variations of viewing angles, as shown in Fig. 1. For the same point, when it transmits to the second position with the perception position stable, the perception would be different as the angle changes. The surface appearance with same tone is different from reflection that is described as luster or specular highlight. Such surface appearance can be best described by terms, e.g., radiant, brilliant, light, stimulus or luminous, of course also in other languages too. Visual evaluation of surface appearance could be perceived by humans with different optical characteristics. Luminosity is now used to show the product luster. And it is also used to represent a total impression of paper model product which gives a better public impression. Various methods of visual evaluation including plain paper product colour with ink in commercial printing, colour appearance attributes using colour appearance model, and 3D computer graphics simulating appearance of paper product surface, are used to evaluate the paper product surface appearance. Although the use of plain paper is popular in colour appearance reproduction or perception, it should be noted that when the luminosity of stereoscopic paper model product is evaluated, various factors would affect the total appearance. These factors include viewing angles, ink changes with the intensity of light reflection, i.e., tone varies. In such case, surface reflection differs according to the tone or ink density. Light reflection on the paper surface with ink often causes absorbance, transmission and multiple reflection between the ink and paper, as shown in Fig. 3.
density or tone, and the illumination environment etc. The factors above hinder the detailed analysis of the visual evaluation and the colour prediction for reproduction in displaying. In order to demonstrate such topic, we would like to take another simple method to describe the "luminance data" distribution which shows the relation between luminance and appearance properties, i.e., complex geometrics of surface and tones. In order to facilitate the description of surface geometrics for paper product, perceived angles related to surface point set positions were used.

For the same surface, it would be perceived with different feeling of luminosity because of the spatial configuration which is shown in Fig. 4a. Surface A and Surface B have same and uniform luminosity if they are perceived in plane under the same view conditions. While we can find that the surface luminosity is not uniform, we also perceive different chroma and luminosity in such configuration. As a result, the stimulus is various even for the same colour tone with different angles referring to the origin in Cartesian Coordinate System as in Fig. 1. For such 3D object like in Fig. 4a, we set different angles for the plain paper to work as the product surface. Of course, there are a couple of differences between the plain paper surface and the real 3D paper product surface, e.g., the roughness is different, Fig. 4b. However, the roughness is not the point discussed in this paper. All surfaces of paper models were produced using the same paper. The surfaces A and B have the same luminosity when they are placed in the same plane. As just discussed above, they are always perceived differently when they are placed in spatial configuration. The key point to describe the difference is to get the relations between the luminosity A and luminosity B. As a result, the luminosity or reflection properties to the preceptor must be measured and characterized to help perceive the appearance and prediction of the paper product surface appearance.

Compared to other substrates, it is easier to get more colours on paper surface than on other substrates surface with different methods. Paper product colour can be performed by printing method, coated method or even papermaking method, etc. This article is to identify essential components of the luminosity of 3D paper model product including two processes: luminosity measurement and analysis. A method for perception of surface luminance using a special device and artificial paper model product printed with different tones for the purpose of improving the precision of evaluation is proposed in this paper. The advantage of this method lies in the fact that the paper properties could be obtained using traditional methods, and vivid tones and appearance can be obtained and accessed. Analysis was used to assess luminosity and the relationship of luminosity to the physical amount of reflection or radiation and colour values was analyzed. In addition, the luminosity on paper model surface perceived from different viewing angles was assessed. The luminosity distribution was evaluated on the four primary colour tones on paper product surface. Finally, the results of the luminosity distribution were analyzed in a colour space. The relationship between the luminosity and paper product surface properties, i.e., paper surface position set and tone value, were discussed in this paper.

In the following, the first stage is to perceive the detailed luminosity using different tones and viewing angles. We made paper model samples printed with inks and measured its spectral reflection and radiation characteristic. Furthermore, a special design for this experiment with a group of experimental devices including radiometer, spectrophotometer, colour printer were developed to perceive and evaluate the appearance of the paper model products at different conditions of viewing angle and various tones. Both parameters could affect the luminosity perception. In fact, the illumination may be fixed for the paper model is always perceived with specific lighting configurations. Then the relationship between the luminosity and the surface reflection characteristics were investigated. The third stage is to summarize the luminosity data and analyze the factors in CIE 1931Yxy colour space.

3 REFLECTION SPECTRAL RADIANT MEASUREMENT OF PAPER SAMPLES WITH DIFFERENT TONES

3.1 Paper Samples Preparation

Office paper is used as the build material which is very different form expensive materials, e.g., plastic or chemically infused powder. And office paper used in this article is ordinary, affordable and ubiquitous, which is always used in traditional printing. Four primary colour tones, cyan, yellow, magenta and black, were used to print on plain paper from 10% to 100% with step of 10%, which is shown in Fig. 5a. And they were set as the surface of paper model. It was maintained at a constant illumination, D65, and had a constant paper surface reflectance. And paper samples with the same tone while different perceived angles are shown in Fig. 5b. The rotation equipment to change the perceived angles like in Fig. 5b, rotating bracket, can also be seen in Fig. 5c. The samples were set on the rotation equipment with angles from 5 degree to 85 degree. The plain paper surface reflection spectral is showed in Fig. 6. It is easy to measure the two-dimentional spectral reflection with spectroradiometer or CS2000.
be able to rotate around a bracket designed in the experiment. The configuration diagram is shown in Fig. 7.

The luminance of paper model sample is at the same conditions of illumination and geometry as the visual evaluation. A standard illumination with colour temperature of 6500K was used as a light source. The measurement area and lighting area were set in a dark room under the standard observation box, Fig. 7. Here the illumination level is set as 600lx, and the luminance value was 120 cd/m² under the normal incidence and viewing situations.

![Figure 5](image)

3.2 Measurement design

A spectroradiometer (Konica Minolta), CS-2000, was used to measure the spectral radiance factor of paper product surface. Several measure sensor models are also used in the experiments. The sensor position, i.e., CS2000, and light source position, standard observation environment, are fixed. And the sample position is set to

4 RESULTS AND DISCUSSIONS

Although the incidence angle is an important parameter in visual assessment, it should be noted that incident light is fixed in a stable position. The spectral curve is showed as a function of viewing angle. Furthermore, another term, tone, is an important factor. To classify this point clear, the tone factors were also described. The visible range and the stimulus were plotted as a function of the tones under the same perceived angle.

4.1 Luminosity with Angle Changes

For luminosity, the angle of 30° has the maximum value, Fig. 8. The radiance intensity perceived would have a peak at the same tone. For the tone factor, the stimulus decreases obviously with the tone increasement. For Cyan, the maximum value difference is $\text{diff}_{\text{max}} = 23.61$, while it is less obvious than the minimum value difference which is $\text{diff}_{\text{min}} = 43.59$ for every tone and viewing angles. And we can also find that the stimulus is linear to the tone change in general. The stimulus is less sensitive on 30° than that on other degrees.

For Magenta, the maximum value difference is $\text{diff}_{\text{max}} = 22.74$, while it is less obvious than the minimum value difference which is $\text{diff}_{\text{min}} = 43.14$ for every tone and viewing angles. And it is obvious that it has the similar situation to the Cyan. The tone 40% and 90% have small differences from that in Cyan. They interact with other tone stimulus.

For Yellow, the maximum value difference is $\text{diff}_{\text{max}} = 3.4$, while it is less obvious than the minimum value difference which is $\text{diff}_{\text{min}} = 11.67$ for every tone and viewing angles. We also can find that the stimulus $Y$ is less

![Figure 6](image)

![Figure 7](image)
sensitive than other tones. And it showed that the angle has more complex effect on the Y stimulus.

For Black, the maximum value difference is $\text{diff}_{\text{max}} = 22.26$, while it is less obvious than the minimum value difference which is $\text{diff}_{\text{min}} = 52.51$ for every tone and viewing angles. It is still like that in Cyan and Magenta, however at the $\text{diff}_{\text{min}}$ position, it shows the smaller angle is more sensitive to perception than that in other colour tones.

4.2 Luminosity with Tone Changes

For luminosity, it decreases with tone increasement obviously no matter what the perceived angles change except for Yellow tone. And the luminosity for 30°, it has the highest luminosity and is less sensitive to the tone change, of course not included in Yellow tone.
In Fig. 9, it is easy to find that all the tones have similar effect on stimulus under different perceiving angles except the yellow tone, though there are some differences among them. In Cyan, Magenta and Black, the angle 30° has the highest stimulus values compared to other angles and is recognized easily. For Yellow tone, we found that the stimulus is very different from the other three tones. The 30° is less sensitive than that in other tones. And the stimulus is obviously higher than that in other tones, e.g., the stimulus starts from 50 while others start from 10 or so. Furthermore, the stimulus changes insensitively in Yellow tone compared to other three tones.

4.3 Luminosity with Dual Terms

From both terms analysis, tone and angle, we found that the luminosity, or other terms used to describe the intensity of perceived lightness of the paper model surface under such configuration and viewing conditions, is affected by two main terms. It is a dual variable function which is composed of tone and angle. It is shown in Fig. 10. From the contour lines, we also can find that the relations among perceived luminosity, tone and angle are layered, segmented and nonlinear. And we will do another research to find the relations among them and try to model them in another paper.

4.4 Perceiving Reflectance Intensity

From the experiment, we found that no matter the angle and tone change or not, the reflectivity is also similar. So, we only take one group charts to give the analysis. Although both angle and tone are different, the reflectance has similarity to the plain paper. It is less affected by the dual terms in this paper. In Fig. 11, what we perceived is quite consistent with the measurement data. It showed that reflectivity would change less or have similar properties like that in plain paper.
4.5 Colour Coordinates in CIE1931XYZ Space

For coordinates shown in Fig. 12, Cyan, Yellow and Black have better equilibrium distribution in colour space, except the Magenta. It shows that no matter the perceived angle or tone changes, its chroma keeps consistent in the same hue angle while its luminosity would change. And the Magenta is easily to be affected by the perceived angles and the tone varies. And Yellow is less affected by that. In fact, this is always consistent with the factual perception and other analysis.

Figure 12 Coordinates of primary colours with different tones

5 CONCLUSION

The luminosity of paper model samples with different perceived angles and tones, was represented in this paper. Concerning the observation geometries designed in the experiment, the luminosity was perceived at the specular reflection angle and specular tone. The luminosity perception is sensitive to the perceived angle and surface tones. The colour perception of the same point on the surface will change with the perception angle. The perception of luminosity in this experiment still changes even with extreme lightness or extreme chroma. And there is a highlight point with angle of 30°.

It is possible to develop a mathematical model to predict the luminosity and chroma perception for paper model product by controlling the perception angles and the point tones which could predict a good colour representation on stereoscopic paper product surfaces. However, the prediction process and model are another topic in the coming research. It will be shown in next paper works.
