ABSTRACT

In this research there were studied the effects of NaCl-induced salinity and environment temperatures on germination and seedlings growth of domestic poppy. The study was conducted in the controlled conditions in the plant growth chamber. There were applied different concentrations of NaCl (0 mM (control), 50 mM, 100 mM and 150 mM) and environment temperatures (10°C, 15°C and 20°C). The 50 seeds of domestic poppy cultivar (Detkovac) were sown in 4 replicates on the filter paper. The germination energy was determined on the 5th day and total germination rate and seedlings morphological characteristic were determined on the 10th day. At the 5th day germination energy was on average 28%. It was interesting to note that at the 10°C there were no germinated seeds after 5 days at all salinity treatments and also, at the salinity level of 150 mM NaCl at every temperature. The average germination rate (on 10th day) of domestic poppy seeds were 52% and it varied from 30% (150 mM NaCl and 20°C) to 90% (0 mM NaCl and 15°C). Different salinity of water solution had a very significant ($p < 0.01$) influence on stem, root and total length (cm) of seedlings. The average root length was 1.3 cm and it varied from 0.9 cm (100 mM NaCl) to 1.8 cm (0 NaCl). The average stem length was 1.8 cm. The longest stem was found at control (2.7 cm), and between 50 and 100 mM of NaCl the difference was not significant and stem length averaged 1.4 to 1.3 cm depending on the temperature. Average total poppy seedlings length of this study was 3.0 cm and it varied from 4.5 cm at the control to 2.3 cm at 100 mM NaCl. With regard to temperatures, there was no significant differences found in root and total length of poppy seedlings, but the differences were very significant ($p < 0.01$) for stem length. The longest poppy seedlings were measured at 20°C and 0 mM NaCl (4.9 cm), while at 10°C and at 0 or 50 mM NaCl, seedlings were less than 0.1 cm. Seeds were not germinating

at all on 10°C on both, 100 and 150 mM NaCl. Generally, salinity reduced germination energy and germination rate and seedlings length. Results may indicate that seeds are mainly affected by osmotic stress and therefore it is not recommended to cultivate poppies on soils with excess salts.

Key words: germination, NaCl, poppy, morphology, temperature

SAŽETAK

U ovom istraživanju analizirani su učinci saliniteta (NaCl) i temperatura na klijavost i rast klijanaca domaćeg maka. Postojale su različite koncentracije NaCl (0 mM (kontrola), 50 mM, 100 mM i 150 mM) i provedene temperature (10 °C, 15 °C i 20 °C). Istraživanje je provedeno u kontroliranim uvjetima u fitotronu. U 4 ponavljanja posijano je po 50 sjemenki domaće sorte maka (Detkovac) na filter papir. Energija klijanja utvrđena je 5. dan, a ukupna klijavost i morfološka karakteristika klijanaca maka nakon 10. dana. Peti dan energija klijanja bila je u prosjeku 28%. Bilo je zanimljivo ustanoviti da na 10 °C nije bilo klijavog sjemena nakon 5 dana na svim tretmanima zaslanjenosti, a također i na razini 150 mM NaCl pri svakoj temperaturi. Prosječna ukupna klijavost (10. dan) domaćeg sjemena maka iznosila je 52% i varirala je od 30% (150 mM NaCl i 20 °C) do 90% (0 mM NaCl i 15 °C). Različita zaslanjenost vodene otopine imala je vrlo značajan utjecaj ($p < 0,01$) na porast stabljike, korijena i ukupnu duljinu (cm) klijanaca. Prosječna duljina kroijena iznosila je 1,3 cm i varirala je od 0,9 cm (100 mM NaCl) do 1,8 cm (0 NaCl). Prosječna duljina stabljike bila je 1,8 cm. Najdulja stabljika izmjerena je na kontroli (2,7 cm), dok između 50 i 100 mM NaCl razlike nisu bile značajne. Ukupna duljina klijanaca maka u ovom istraživanju iznosila je 3,0 cm i varirala je od 4,5 cm na kontroli do 2,3 cm pri 100 mM NaCl. S obzirom na temperature, nisu utvrđene značajne razlike u korijenu i ukupnoj duljini klijanaca maka, ali razlike su bile vrlo značajne ($p < 0,01$) za duljinu stabljike. Najduži klijanci maka izmjereni su na 20 °C i 0 mM NaCl (4,9 cm), dok su na 10 °C i na 0 ili 50 mM NaCl klijanci bili manji od 0,1 cm. Sjeme uopće nije klijalo na 10 °C, a ovisno o salinitetu pri 100 i 150 mM NaCl. Općenito, zaslanjenost je smanjila energiju klijanja, brzinu klijanja i duljinu klijanaca. Ova domaća sorta maka bila je vrlo osjetljiva na relativno visoke koncentracije soli, što ukazuje na to da sjeme uglavnom utječe na osmotski stres te se ne preporuča uzgajati na tlima s viškom soli.

Ključne riječi: klijavost, NaCl, mak, morfologija, temperatura

INTRODUCTION

There is an increasing interest in poppy cultivation for culinary purposes, especially in old domestic varieties in the Republic of Croatia. Zemanek et al. (2009) states that garden poppy (*Papaver somniferum* L.), probably originating from Asia Minor, is planted as a medicinal and decorative plant, and provides edible seeds for human consumption. Procházka et al. (2012) states that poppy is grown mainly for its content of opium and oil seed, and in Europe, poppy seeds are mostly used for confectionary. Oil contents change considerably depending on the origins of varieties and on the color of the seeds. The reported values of oil contents of the seeds are between 41.4–49.1% in India and 44.0–57.0% in Turkey (Azcan et al., 2004). Worldwide, poppy seed is harvested on average of 121,003 ha and average seed yield was 0.71 t ha⁻¹ from 2015 to 2017 (FAOStat, 2019). In the Europe, during the period from 2015 to 2017 the average poppy harvested area was 82 368 ha and the seed yield was 0.63 t ha⁻¹. The large producers are Czech Republic, France, Spain, Hungary, Germany and Netherlands (FAOStat, 2019). Lošák et al. (2009) constate that among the EU, the Czech Republic has a long tradition of poppy seed production for pharmaceutical purposes and ranks among the most important producers and exporters of poppy seed in Europe.

According to Pospíšil (2018) during the last few years, the Republic of Croatia has shown an interest in growing oil poppies on larger areas. According to Agronet (2021) there was about 90 ha of poppy areas in 2020 in conventional farming and around 10 ha in organic farming.

In the Republic of Croatia for the spring sowing period, the sowing must be done in early spring, no later than April 1, or when the soil is heated to 5°C (Pospíšil, 2013). According to Cope and Drost (2012) the seedbed should remain moist until plants emerge, which takes 7 to 28 days depending on soil temperature. Brčić et al. (2016) stated that cultivars (Opal, Lazur, Major, Matis, Gornji Bogičevci and Beli Manastir) of spring sowing had the average seed yield about 850 kg ha⁻¹. Poppy seeds for household use are mostly imported (for cakes making), but poppy seeds used in the bakery and confectionery industries and for culinary purposes are also increasingly imported.

Production of poppy in the Republic of Croatia, due to its alkaloid content, is subject to special government control and must be reported to the Ministry of Agriculture (OG 80/2013 and 39/2018). The person who grows the poppy is obliged to report the poppy cultivation to the Ministry of Agriculture of the

Republic of Croatia or the agricultural inspection no later than 30 days from the date of sowing.

The global problem of soils salinization is increasing, what leads to decrease of average yields for most major crops (Cuevas et al., 2019). Soil salinity is a common problem especially in irrigated areas with low rainfalls (Holik et al. 2017). Salt and osmotic stresses are responsible for growth under salinity conditions through both inhibition or delayed seed germination and seedling establishment. Soil liquid phase or soil solution plays an important role in soil formation and development (Zebec et al., 2017), its dynamics and specific soil characteristics. It is important that the liquid soil phase is neither high nor low in salts, as most crop plants prefer moderate salt concentration. The uses of nitrogen and potassium fertilizers causes an infrequent increase in salt concentrations in soil, which is detrimental to plant growth and development. The form of the N in fertilizers is important for potential salinization, so some studies indicate that increased nitrate in nutrient solution would decrease chloride uptake and its accumulation (Esmaili et al., 2008). According to Nachshon (2018) the major sources of solutes in agricultural environments are the soil itself, and the parent geological material, shallow and salt rich groundwater and salt rich irrigation water.

The mechanisms of the salt tolerance in seeds are relatively poorly understood. Salt tolerance is mostly associated with high intracellular concentrations of both Na^+ and Cl^- ions which can inhibit critical metabolism of the plant cells (Lisjak et al., 2015; Wu et al., 2015). Also, secondary effects of salinity are oxidative damage due to generation of ROS – reactive oxygen species (Purty et al., 2008; Isayenkov et al., 2019).

Successful germination is crucial in the life cycle of the plants. Especially, the emergence under field conditions is influenced by several abiotic factors such as salt stress, temperature, moisture, pH, seedbed preparation, allelopathic effect etc. (Tucak et al., 2016; Lisjak et al., 2015; Bukvić et al., 2015; Saraf et al., 2017; Bukvić et al., 2018; Andelić et al., 2018; Baličević et al., 2018; Rojnica et al., 2019; Sytykiewicz et al., 2019), which can decrease the number of plants per unit area. The NaCl salinity stress consistently decreased the rate of germination of most field crops (Al-Tawaha et al., 2018; Rysbekova et al. 2019).

There are no reported seed germination tests of Croatian domestic poppy cultivars under saline conditions. In the Republic of Croatia, the poppy can be sown as winter or spring crop.

The aim of this research was to study the effects of different constant temperatures (10°C, 15°C and 20°C) and different water solution salinity induced by NaCl: 0 mM (control), 50 mM, 100 mM and 150 mM), on domestic poppy cultivar from Detkovac.

MATERIALS AND METHODS

In this study the domestic cultivar of poppy was used. The name of the cultivar was given according to the place where the cultivar was found. The cultivar originates from the middle part of continental area of the Republic of Croatia from the place named Detkovac (45°88' North and 17°59' East). Cultivar was entered in the CPGRD database at code IND00069.

The effects of NaCl salinity and temperatures on germination and seedlings growth of domestic poppy cultivar were studied. There were applied different concentrations of NaCl (0 mM (control), 50 mM, 100 mM and 150 mM) and different but constant temperatures of environment (10°C, 15°C and 20°C) during the germination test. These temperatures were chosen to find the minimum temperature for cultivar Detkovac germination.

The germination test was done according to the International Seed Testing Association – ISTA (ISTA, 2006). The 50 seeds of domestic poppy cultivar were sown in 4 replicates on the filter paper. The filter paper (Munktell, 80 g/qm) was moistened with 25 ml water solution. Afterwards the 50 seeds of domestic poppy cultivar per replication were sown on each filter paper and then rolled and put into plastic bag. The seeds were sown in 4 replicates. The study was conducted in the controlled conditions in the plant growth chamber (Fitoclima, Aralab). There were three different temperatures: 10, 15 and 20°C for 10 days. The germination test was done in 24 h dark conditions.

The germination energy (%) was determined on the 5th day and total germination rate (%) and was determined on the 10th day. Also, after 10 days the shares of normal, abnormal and non-sprouted seeds were determined. Afterwards, the length of root, stem and total length (cm) of 10 normally developed seedlings, were measured.

The ANOVA was performed using SAS 9.4 Software-a (SAS Institute Inc.). The LSD test was used to calculate the differences between the means at $p < 0.05$ and $P < 0.01$. Simple linear regression was done to show relationship between length of root and stem of seedlings. For average total length of domestic poppy

seedlings, the total length of root and stem the seedlings less than 0.1 cm and treatments of non-sprouted seeds (at 10°C for 100 and 150 mM) was not taking into ANOVA procedure and LSD test for calculation the differences between means (Table 1).

RESULTS AND DISCUSSION

Germination energy and germination rate (Figure 1) was the highest at control treatment (0 mM NaCl) and it averaged 55% and 77%, respectively. The seeds were not sprouted after 5 days at 150 mM NaCl and at 10°C (0%). With increase of salinity, the germination energy decreased and it was 14% at 50 mM NaCl and 8% at 100 mM NaCl. Germination rate with regard to salinity was also decreased with higher salt concentration. At 150 mM NaCl the total germination rate was 20%, but the seedlings developed were less than 0.1 cm. Seeds were not germinated at all on 10°C on both, 100 and 150 mM NaCl.

Fig. 1 Germination energy (%) and germination rate (%) of domestic poppy cultivar regard to salinity and temperature (error bars show confidence intervals of the 5%)

Grafikon 1. Energija klijanja (%) i ukupna klijavost (%) domaće sorte maka ovisno salinitetu i temperaturi (stupići označavaju intervale pouzdanosti od 5%)

The highest share of normally developed poppy seedlings (Figure 2) was at control (54%), and with increased level of salinity the normal developed seedlings decreased to about 20% at 50 mM NaCl and 13% at 100 mM NaCl, whereas at 150 mM NaCl there was no normally developed seedlings at all. With regard to temperature, the highest share of normal seedlings was at 20°C (42%), and the highest share of non-sprouted seeds were at 10°C (75%). The highest share of abnormal domestic poppy seedlings was at 100 mM NaCl and 15°C (80%) and the lowest at control, both for 15°C and 20°C (7%). Kumar et al. (2010) for 6 genotypes of poppy at 20°C in-situ (Petri dish) and ex-situ (soil of earthen pot) after 10 days found that the average percentage of germination for opium poppy genotype Sanchita was 93.50 and 66.25%, genotype Vivek was 93.20% and 65.75%, genotype Sampada was 92.40 and 55.20%, genotype Sujata 85.75% and 49.47% and of genotype Sweta was 77.05 and

39.00%, respectively. Karlsson et al. (2007) found that for *Papaver* species (*P. argemone*, *P. rhoeas*, *P. dubium* ssp. *dubium* and *P. dubium* ssp. *lecoqii*) in warmer climate the more germination occurred in autumn instead of spring. According to Pospišil (2013) a minimum temperature for poppy germination is 2 to 3°C and the optimum is 20°C. Author stated that poppy is very sensitive to low temperatures and that in the field conditions the poppy seed will emerge at 10-11°C after 4 or 6 days. But in this study after 10 days the seeds were not sprouted at all on the filter paper, even at the control treatment without NaCl.

Fig. 2 The share of normal, abnormal domestic poppy seedlings and non sprouted seed regard to temperature and NaCl salinity

Grafikon 2. Udio normalnih, abnormalnih klijanaca maka i nekljalog sjemena s obzirom na temperaturu i salinitet NaCl

On the temperature treatment of 10°C and at 0 and 50 mM NaCl, the length of seedlings roots and stems were not measured because they were less than 0.1 cm of total length. Also, at 100 and 150 mM water solution of NaCl and at 10°C, the seeds were not germinated at all. At higher temperatures, of 15°C and 20°C, and at the highest salinity level (150 mM NaCl), seedlings were also less than 0.1 cm, and therefore not including into measurements.

The average length of domestic poppy seedlings was 3.0 cm. Different salinity had very significant influence ($p < 0.01$) on total seedlings length and the length of root and seedlings stem (Table 1). The longest seedlings were developed at the control treatment (4.5 cm) and the smallest at 100 mM NaCl (2.3 cm). Similar was with root and stem length. Thus, on the 10th day, the longest roots and stems had the seedlings at control (1.8 cm and 2.7 cm, respectively) and the smallest seedlings roots and stems were developed at 100 mM NaCl (0.9 cm and 1.3 cm, respectively).

Single linear regression showed very significant relationship between stem and root length only at 100 mM NaCl (Figure 3). Generally, in the unique salinity and similar temperature conditions there were poor regressions between the seedlings roots and stems lengths. Even though the R^2 was small, according to simple regression analysis for every centimeter increment of root length, the stem length decreases for 0.25 cm at 100 mM NaCl ($y = -0.25x + 1.57$). Lošák et al. (2009) reported that the poppy crop has short vegetation period and weak root system.

Despite the importance of germination under salt stress, the mechanisms of salt tolerance in seeds are relatively poorly understood (Zhang et al., 2012). In this study, high salinity treatments at low temperatures were associated with lower germination. This, unfortunately, makes it impossible to know whether, at low temperatures, salt decreased the final germination percentage in these cases, or merely delayed germination. In either case, salt seemed to have no toxic effects for domestic poppy at concentrations up to 50 mM NaCl. For the oilseeds, Matthees et al. (2018) state that alternative oilseeds as winter camelina (*Camelina sativa*) and cuphea (*Cuphea viscosissima* x *Cuphea lanceolata*) were tolerant to salinity (8.0 and 3.1 dS m⁻¹), whereas winter pennycress (*Thlaspi arvense* L.) and calendula (*Calendula officinalis*) were moderately tolerant to salinity (5.9 and 2.7 dS m⁻¹) and that these oilseeds show potential for adoption in saline soils.

Even though there was observed negative effect of salinity on poppy seedlings growth, for other species Na⁺ can have a positive effect. Michalak et al. (2016) in the research of algal compost extract (originating from sea) on *Lepidium sativum* germination, found the positive effect on plant cultivation.

In this study, germination of domestic poppy seeds was significantly affected ($p < 0.01$) by salinity and interaction of salinity and temperatures (Table 1) for the morphological characteristic of seedlings (total length, root and stem length).

Although species from families *Solanaceae* and *Brassicaceae* are not typical halophytes, Bojović et al. (2010) found that seeds of *Capsicum annum*, *Solanum lycopersicum*, *Brasica oleracea* and *Sinapis alba* germinate only in the lowest concentration of NaCl (200 mM), while at higher concentrations of salt (400, 600 and 800 mM of NaCl) seeds germination were inhibited. But for some other oilseed species, (Miyamoto et al., 2012) found that Canola (*Brassica napus*) and safflower (*Carthamus tinctorius*) were salt-tolerant during germination, but emergence was curtailed owing to soil crusting. Further, author found that Camelina (*C. sativa*) germinated well, but probably due to weak hypocotyl the emergence was poor and for the authors found Field pennycress (*Thlaspi arvense*) and Lesquerella (*L. fendleri*) salt sensitive because they could not germinate in NaCl solutions higher than 50 mM. For increase the resistance of oilseed rape (*Brassica napus* L.) plants to salt stress, (Efimova et al. 2014) use the brassinosteroids (24-epibrassinolide, EBL) and the authors have found that after 3 weeks salinization inhibited plant height by 33–35% compared to the control, but also reduced leaf area and plant fresh and dry weight. For the brassinosteroides, authors found involvement of brassinosteroids increment in the development of salt tolerance (24-epibrassinosteroids (24-epibrassinolide and 24-epicastasterone), 24S-methyl-brassinosteroids (brassinolide and castasterone), and 28-homobrassinosteroids (28-homobrassinolide and 28-homocastasterone).

Other species like legumes have also shown the low tolerance for the salt stress (Kaya et al., 2008; Rady et al., 2017). Kaymakanova (2009) in the study of NaCl and Na₂SO₄ salinity at germination and early seedling growth of (*Phaseolus vulgaris* L.), found the inhibiting effect of Na₂SO₄ is by 20% stronger than that of NaCl.

In cereals, Panuccio et al. (2014) found that for quinoa lower concentrations (25, 50, 75 and 100 %) of salts (NaCl, CaCl₂, KCl and MgCl₂), increased the germination rate but not the germination percentages, compared with control (pure water). In horticulture production, Montana et al. (2014) found that different NaCl concentrations (0, 30, 60, 90, and 120 mM) affected the accumulated germination and the percentage of germination of purple passion fruit seeds (*Passiflora edulis* Sims.). For greenhouse grown eggplant (*Solanum melongena*, L.), Chartzoulakis and Loupassaki (1997) found that plant height and leaf area were reduced significantly (P = 0.05) at salinities of 25, 50, 100 and 150 mmol NaCl and that Cl⁻ in leaf was always present at higher tissue concentrations than Na⁺.

CONCLUSIONS

The investigated domestic poppy cultivar was very sensitive to increase of salt concentrations, indicating that seeds are mainly affected by osmotic stress and therefore we can not recommended to cultivate it on soils with excess salts. Even though this study was based only on the morphological parameters, further studies are needed to unravel the details of Na⁺, and especially Cl⁻, uptake mechanisms for the domestic poppy cultivars. Even though the longest seedlings were developed at 20°C (4.9 cm), there was no significant difference in total length of seedlings at 15°C (4.1 cm).
